## **ABSTRACT**

### **A GENETIC ALGORITHM FOR p-HUB CENTER PROBLEM WITH STOCHASTIC SERVICE LEVEL CONSTRAINTS**

Eraslan Demirci, Şükran

M.Sc., Department of Industrial Engineering

Supervisor: Asst. Prof. Dr. Sedef Meral

December 2010, 170 pages

The emphasis on minimizing the costs and travel times in a network of origins and destinations has led the researchers to widely study the hub location problems in the area of location theory in which locating the hub facilities and designing the hub networks are the issues. The p-hub center problem considering these issues is the subject of this study. p-hub center problem with stochastic service level constraints and a limitation on the travel times between the nodes and hubs is addressed, which is an uncapacitated, single allocation problem with a complete hub network.

Both a mathematical model and a genetic algorithm are proposed for the problem. We discuss the general framework of the genetic algorithm as well as the problem-specific components of algorithm. The computational studies of the proposed algorithm are realized on a number of problem instances from Civil Aeronautics Board (CAB) data set and Turkish network data set. The computational results indicate that the proposed genetic algorithm gives

satisfactory results when compared with the optimum solutions and solutions obtained with other heuristic methods.

Keywords: Hub Location, P-Hub Center Problems, Stochastic Service Level Constraints, Genetic Algorithms

## ÖZ

# STOKASTİK HİZMET DÜZEYİ KISITLI p-ANA DAĞITIM ÜSSÜ MERKEZLİ PROBLEM İÇİN BİR GENETİK ALGORİTMA

Eraslan Demirci, Şükran  
Yüksek Lisans, Endüstri Mühendisliği  
Tez Yöneticisi: Yrd. Doç. Dr. Sedef Meral

Aralık 2010, 170 sayfa

Çıkış ve varış noktalarının oluşturduğu ağlarda maliyetleri ve ulaşım sürelerini enazlamaya verilen önem; araştırmacıları, ana dağıtım üslerinin konumlandırıldığı ve ana dağıtım ağının tasarlandığı yerleşim kuramı çerçevesindeki ana dağıtım üssü konumlandırma problemini daha kapsamlı çalışmaya yöneltmiştir. Bu konuyu ele alan p-ana dağıtım üssü merkezli problem bu çalışmanın konusudur. Stokastik hizmet düzeyi kısıtının ve ana dağıtım üsleri ile varış/çıkış noktaları arasındaki taşıma süresi üzerinde kısıt olan p-ana dağıtım üssü merkez problemi üzerinde çalışılmıştır. Bu problem tam bağlantılı ana dağıtım üssü ağında, kapasite kısıtı olmayan, tek atamalı p-ana dağıtım üssü merkez problemidir.

Üzerinde çalışılan problem ile ilgili olarak bir matematiksel model ve genetik algoritmaya dayalı bir sezgisel yöntem geliştirilmiştir. Genetik algoritmanın genel çerçevesi ile birlikte, problem-özgü bileşenler tartışılmıştır. Önerilen yöntem ile Amerika Sivil Havacılık Kurulu (CAB) veri kümesi ve Türkiye Ağrı veri kümesinden elde edilen çeşitli problem örnekleri üzerinde önerilen yöntem ile sonuçlar elde edilmiştir. Genetik algoritma ile elde edilen sonuçların;

optimum sonuçlar ve diğer bazı sezgisel yöntemlerden elde edilen sonuçlar ile karşılaştırıldığında tatmin edici düzeyde olduğu görülmüştür.

Anahtar Kelimeler: Ana Dağıtım Üssü Konumlandırma, p-Ana Dağıtım Üssü Merkezli Problem, Stokastik Hizmet Düzeyi Kısıtlı, Genetik Algoritma.

## **ACKNOWLEDGEMENTS**

First of all, I would like to thank my supervisor Ass. Prof. Dr. Sedef Meral for her kind guidance, cooperation, encouragement and advice throughout the study. I would also like to express appreciation to her for her trust and supporting in a friendly atmosphere that inspired creativity and motivation.

I sincerely thank TÜBİTAK and the managers for giving me the chance to complete my Master of Science degree.

I would like to present special thanks to helpful Erhan Girgin for his support for the computational part of this work.

I express my deepest gratitude to my father Hakkı Eraslan, my mother Süheyla Eraslan and my sweet sister Yasemin Eraslan for their endless love, moral, and encouragement throughout my whole life.

Finally, I would like to thank my darling Yücel Demirci for his existence, trust, endurance and everlasting love. I always feel his encouragement and that he will always be with me whenever I need him.

# **CHAPTER 1**

## **1. INTRODUCTION**

The aim of the hub location problems is to reduce the costs or transportation times of a given network. Locations for the hubs and allocations of the non-hub nodes to the hubs are determined in the hub location problems. The service is given by or at a facility in the location problems. The difference of the hub location problems from the other location problem is that, “service” means the transferring of the goods, people or information between an origin node and a destination node. Each pair of origin and destination nodes represents a different service that needs to be provided. Thus, packages moving from node A to node B are not interchangeable with packages moving from node C to node D (Daskin, 1995, p.349). Hub location problems are proper for the networks that aggregation and disaggregation of flows at certain locations are possible (Kara and Tansel, 2000). The hubs serve as connection, transshipment and classification points. Generally establishing a complete network for transporting the commodities directly between origin and destination nodes is extremely costly. Instead of having a complete network with direct links between each origin node and each destination node, hub facilities are constructed in order to benefit from the economies of scale of transferring larger flows. Flows belonging to the same origin node are aggregated and transferred to the same hub and then are consolidated with the flows from the remaining origin nodes that will be transferred to the same destination node. Some typical application areas of the hub location problem are airline passenger travel, cargo delivery and message delivery in computer communication networks (Kara and Tansel, 2000).

There are  $n$  nodes and the amount of flow between each pair of nodes is given. The aim is to determine the locations of the hubs among these  $n$  nodes and the allocations of these  $n$  nodes to the selected hubs so as to minimize the costs. The costs considered in these problems can be the transportation costs of the flows, the fixed costs of the network, the path length of the transportation or the time of the transportation. The assumptions often valid in the hub location literature are as follows: There are economies-of-scale for the inter-hub connections reflected by a discount factor,  $\alpha$ , and there is a complete network for the hubs.

Although the basic environment of the hub location problem is as defined above, different characteristics of environments for hub locations and non-hub node allocations cause to diversify the hub location environment. The literature about the hub location problems is examined in a classification with regard to these problem characteristics in the following sections.

This study is concerned with the p-hub center problem, which considers locating  $p$  many hubs and allocating the remaining non-hub nodes to these located hubs. The p-hub center problem is similar to the p-center problem in minimizing the adverse affects of the worst case. The aim is to find  $p$  many hub locations and the remaining non-hub nodes allocations to these located hubs in order to minimize the maximum length of the links or maximum cost of the links. Center type of location problems resembles real life situations like the problem of emergency aid facilities or vehicles locations.

The p-hub center problem is NP-hard (Kara and Tansel, 2000) and classical mathematical formulation based approaches are usually not satisfactory especially for the large problems.

Our aim in this study is to propose a formulation for the p-hub center problem with stochastic service level constraints, considering that the travel times on the links may be stochastic rather than being deterministic. Firstly, we formulate

the problem as an integer programming model. However, because of the incapability of the commercial solvers in solving especially the large size problems, we propose to the use of metaheuristics. For this purpose, we apply a genetic algorithm (GA) based solution approach for our p-hub center problem.

In the following chapters, the details of our study are presented.

In Chapter 2, an overview of the literature of the hub location problems is included based on a classification scheme.

In Chapter 3, the problem environment of our problem is explained in detail and the related integer programming formulation is presented.

Chapter 4 presents our solution method for the p-hub center problem with stochastic service level constraints. The solution procedure is based on Genetic Algorithms, and before describing the proposed algorithm, the brief overview and general components of the Genetic Algorithms are given.

Chapter 5 includes the computational study. The test problems used in the computational study are first defined. Then the GAMS results for small sized problems and aggregation and decomposition based heuristic results for large sized problems are obtained for evaluating the performance of our method.

Chapter 6 concludes our study by briefly indicating the significant parts of our study and pointing some directions for future researches.

## CHAPTER 2

### 2. LITERATURE REVIEW

#### 2.1 HUB LOCATION

The hub location problems are network design problems, which has  $n$  nodes and the flow among each origin and destination node pair is given. In a simplest network, these flows can be handled by connecting each pair of nodes with a complete network among them. However, this will result in a highly inefficient network in terms of both economical and managerial issues. For an  $n$  node network, if a fully connected network is constructed, then this will result in  $n(n-1)/2$  connections, which will be a costly and a difficult network to manage. On the other hand, if a network with one hub among these  $n$  nodes is constructed, this will result in a network of  $(n-1)$  connections. In Figure 1.1, a complete network for 5 nodes is illustrated, whereas in Figure 1.2, the network with one hub is illustrated. Although in these examples we have a few nodes, it is obvious that the fully connected network is more complicated.

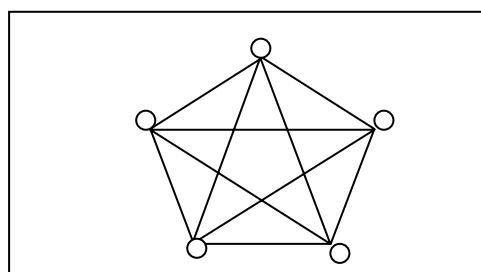

Figure 1.1 A Complete Network for 5 Nodes

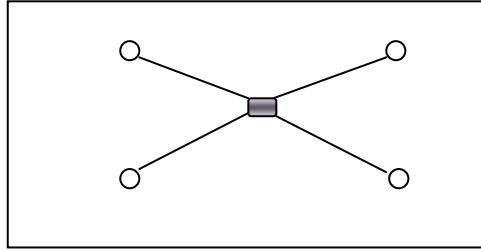

Figure 1.2 One Hub Network for 5 Nodes

There are also drawbacks of the hub location networks; the obvious one of which is the increasing transportation leg for an origin-destination pair; except the case in which either is a hub (Daskin, 1995, p.350). Consequently, the location of the hubs and the allocation of the nodes to these hubs are critical factors for the efficiency of a network and the aim is to locate the hubs among these  $n$  nodes and allocate these nodes to the selected hubs in order to minimize the total costs. The costs associated to these problems can be the fixed costs, the transportation costs, and the path length of the transportation or the time of transportation. The assumptions often valid in hub location literature can be stated as: There is a complete network for the hubs and there are economies-of-scale for the inter-hub connections reflected by a discount factor,  $\alpha$ .

Hub location network problems are first defined in the paper of Goldman (1969). However, the literature on the hub location problem started with O'Kelly (1986a). There exists a wide literature about hub location problems, including several review papers that classify the hub location problems. In our paper, we classify the problem environment according to the classification of Alumur and Kara (2007). In this paper, the hub location problems are classified into four main categories: the  $p$ -hub median problem, the hub location problem with fixed costs, the  $p$ -hub center problem and the hub covering problem. This classification is mainly according to the objective of the hub location problems. However, there are also other variations according to the hub network structure. Some variations result from the assumption about the allocation of

the non-hub nodes. According to these assumptions, the hub location problems can be classified as: single-allocation hub location problems, where the non-hub node is allowed to be assigned to only one hub and multiple-allocation hub location problems, where the non-hub node is allowed to be assigned to more than one single hub. Moreover, the hub location problem environment varies with respect to the links among non-hub nodes: direct links between non-hub node pairs are allowed or the transportation between the non-hub-nodes can be done only via the hubs. In addition, there exist the capacitated and uncapacitated versions of the hub location problems according to whether there exists a capacity constraint for the hubs or for the arcs, or not.

### **2.1.1 The p-Hub Median Problem**

The p-hub median problem is one of the most commonly touched areas of the hub location problems. The number of hubs to be opened is given as  $p$  in this problem. There are  $n$  nodes and the flow among each pair of nodes is given. The aim is to determine the location of the hubs and the route of each pair of nodes denoted by an origin and a destination node so that the total transportation cost is minimized. The p-hub median problem is NP-hard. Furthermore, Kara (1999) shows that the allocation part of the p-hub median problem, for fixed hub locations, is also NP-hard. According to Alumur and Kara (2007), the studies regarding the p-hub median problem can be analyzed in two categories according to the allocation decisions: single allocation p-hub median problems and multiple allocation p-hub median problems.

#### **2.1.1.1 Single Allocation p-Hub Median Problem**

Each non-hub node is allowed to be connected to only a single hub in the single allocation p-hub median problem. The first formulation of the single allocation p-hub median problem is provided by O'Kelly (1987) as a quadratic integer program. He also proposes first two heuristics for that problem, called HEUR1 and HEUR2. In these heuristics, all possible alternatives for p-hub

locations are enumerated. The assignment of the non-hubs to the nearest hub rule is used in HEUR1 and in HEUR2 to the better of the first and the second nearest hubs is used. Furthermore, to present the computational results for these two heuristics, O’Kelly introduces a data set referred as CAB data set. It is based on the airline passenger transports of 25 US cities. This data set has been widely used in the hub location literature.

Aykin (1990) develops a technique for finding the optimal allocations of the nodes to the given hub locations. Klincewicz (1991) examines the single allocation p-hub median problem with a potential set of hubs and develops an exchange heuristic that substitutes other nodes based on local improvement taking account of one substitution and two substitutions at a time. He compares the heuristics with clustering and enumeration heuristics. Then Klincewicz (1992) presents a greedy randomized search procedure heuristic (GRASP) and a tabu search heuristic.

Skorin-Kapov and Skorin-Kapov (1994) develop another tabu search heuristic that emphasizes the allocation part of the problem. The results on the CAB data show that their heuristic is superior to the heuristics of O’Kelly (1987) and the tabu search heuristic of Klincewicz (1992). However, the CPU time requirement is greater. O’Kelly et al. (1995) linearize the quadratic objective function of O’Kelly (1987) for finding a lower bound technique where the triangle inequality is assumed to be satisfied. Later the solutions obtained by Skorin-Kapov and Skorin-Kapov (1994) are validated to be optimal in the work of Skorin-Kapov et al (1996) in which the authors proposes a mixed integer programming formulation. The LP relaxation of this formulation is shown to be tight by Skorin-Kapov et al. (1996).

The single allocation p-hub median problem is first proposed by Campbell (1994b) as a linear integer formulation. He also formulates the p-hub median problem with flow thresholds. After that, he obtains a formulation by setting

the flow thresholds to their maximum values, because in that case each node is allocated to a single hub.

Then, with the obvious result that the multiple allocation p-hub median problem provides a lower bound for the single allocation p-hub median problem, two new heuristics for the same problem called MAXFLO and ALLFLO heuristics are proposed by Campbell (1996). The location decisions are the same in these heuristics; however the allocation decisions are made using different rules.

Ernst and Krishnamoorthy (1996) present a mixed integer LP formulation of the uncapacitated single allocation p-hub median problem (USAphMP). They propose a simulated annealing heuristic and an LP-based B&B algorithm. The B&B algorithm and the proposed heuristic are both tested on the CAB data set and a newly introduced data set called the Australian Post (AP) data set, but they solve only the problems up to 50 nodes. AP data set is based on 200 postal districts of Australian postal delivery. The flows of the AP data set are asymmetrical as opposed to the CAB data set.

Then, Ernst and Krishnamoorthy (1998b) develop a B&B algorithm based on the shortest path approach. They state that their new algorithm is significantly faster and requires less memory than the algorithm of Ernst and Krishnamoorthy (1996) for small values of  $p$ . Problems with 100 nodes for  $p=2$  and  $p=3$  are solved in approximately 228 and 2629 seconds, respectively.

Later, Ebery (2001) presents a mathematical formulation for the single allocation two-hub median problem and for the single allocation three-hub median problem, and he also considers the situation where the hub nodes are fixed.

O'Kelly et al. (1996) discuss the sensitivity of the results to the discount factor  $\alpha$  with a new formulation assuming a symmetric flow data.

Smith et al. (1996) study the modified Hopfield neural network of single allocation p-hub median problem using the quadratic integer formulation of O'Kelly (1987).

Sohn and Park (1997) provide a linear formulation and show that the two hub problem is polynomially solvable. Sohn and Park (1998) present a mixed integer formulation for given hub locations and also consider the fixed costs of the links between non-hub nodes and hubs. Later, Sohn and Park (2000) study the three-hub network single allocation problem with known hub locations as a mixed integer formulation. They show that even for the three hubs, the single allocation problem is NP-hard and study the polyhedral properties of the formulation.

Pirkul and Schilling (1998) construct a Lagrangean relaxation heuristic. They use subgradient optimization of the relaxed model. The constructed heuristic is the most effective heuristic for the single allocation p-hub median problem up to 2007 according to Alumur and Kara (2007).

Abdinnour-Helm (2001) proposes a simulated annealing based heuristic; however, it is shown to perform worse than that of Ernst and Krishnamoorthy (1996).

Aversa et al. (2005) investigate the hub networks in marine transportation. They propose a model for selecting a hub port among 11 potential hub locations. The model is based on the single allocation p-hub median model and the port of Santos in Brazil is selected in the model.

Elhedhli and Hu (2005) propose a model for the single allocation p-hub median problem that has a non-linear convex cost function and they consider congestion at the hubs. They use piecewise linear functions to linearize this model and then apply Lagrangean relaxation to the linearized model. They state that the solutions of the congestion model are more balanced in terms of

the allocation of flows to the hubs when compared with the problem without congestion.

Pérez et al. (2005) provide a hybrid heuristic that combines GRASP (greedy random adaptive search procedure) heuristic and Path-Relinking heuristic for the problem with capacity restrictions. They benefit from the GRASP heuristic proposed by Klincewicz (1992) and GRASP is used for the generation of the population of the Path Relinking. In addition, they propose a Path Relinking heuristic for this problem.

Kratica et al. (2007) propose two genetic algorithm approaches called GAHUB1 and GAHUB2 in order to solve the uncapacitated single allocation p-hub median problem. The genetic algorithms are tested on the CAB and the AP data sets and GAHUB2 outperforms GAHUB1, and GAHUB2 gives all previously known optimal solutions for small and medium sized problems. In addition, the best-known solutions from the literature for large size problems are significantly improved by GAHUB2.

Yaman (2009) considers the three-level (hierarchical) hub network problem with a complete network in the first level, aiming to find the locations of the central hubs and the hubs, and the connections such that the total routing cost of the resulting network is minimized. Yaman (2009) proposes an MIP formulation for the hierarchical single assignment hub median problem; then she obtains a formulation for the hierarchical single assignment hub median problem with time restrictions. She solves these models by GAMS and CPLEX using CAB data set and the Turkish network data set to see the effects of various model parameters on the results.

A summary of the studies on the p-hub median problem is provided in Table 2.1.

### **2.1.1.2 Multiple Allocation p-Hub Median Problem**

In the multiple allocation p-hub median problems, each node is allowed to be assigned to more than one hub. The multiple allocation p-hub median problem is first formulated by Campbell (1992) as a linear integer model. Then, Campbell (1994b) states that there is an optimal solution to the problem with no capacity constraints.

Skorin-Kapov et al. (1996) replace some constraints in the formulation of Campbell (1992) with the aggregate forms of them. The advantage of this formulation is that, it results in tighter LP relaxations. To obtain optimal solutions in the case of no integer solution from the LP relaxation, an implicit enumeration search tree is designated.

Ernst and Krishnamoorthy (1998a) define a new mixed integer formulation and show this formulation to be more effective than that of Skorin-Kapov (1996). Ernst and Krishnamoorthy (1998a) obtain a strong lower bound by adding the violated inequalities of B&B method to the LP. Also, Ernst and Krishnamoorthy (1998a) propose a shortest path based heuristic and an explicit enumeration based heuristic for fixed hub locations. Furthermore, Ernst and Krishnamoorthy (1998b) develop an alternative B&B algorithm obtaining lower bounds from the shortest path problems.

In order to overcome the weak lower bound deficiency of the formulation in Ernst and Krishnamoorthy (1998a), Boland et al. (2004) develop some tightening constraints and preprocessing techniques. The results are improved with these preprocessing techniques and tightening constraints.

An efficient shortest path based heuristic method is proposed by Sohn and Park (1998), for small  $p$  values of the multiple allocation p-hub median problem.

Sasaki et al. (1999) present the multiple allocation p-hub median problem with 1-stop in which the origin-destination pairs is allocated to one hub simultaneously. A greedy heuristic and a B&B algorithm are tested.

Campbell (2009) provides a time-definite model for the multiple allocation p-hub median problem and another time-definite model for the hub arc location problem. Service level constraints on the maximum travel distance between each origin node and destination node are imposed in those models. Both models are solved using CPLEX and the CAB data set. The effects of the time definite service levels are demonstrated on truck transportation in North America.

We summarize the literature on the multiple allocation p-hub median problem in Table 2.2.

### 2.1.2 The Hub Location Problem with Fixed Costs

There is a fixed cost of opening a hub and the number of hubs becomes a decision variable in the hub location problems with fixed costs, unlike the p-hub median problem. The aim is to determine the number and location of hubs and the allocation of the nodes to these hubs in order to minimize the total of fixed and transportation costs.

A quadratic integer program is introduced by O'Kelly (1992a). Then, the first linear formulations of the both capacitated and uncapacitated versions of the single and multiple allocation hub location problems with fixed costs are presented by Campbell (1994b).

Aykin (1994) models the capacitated single allocation hub location problem with fixed costs in which the direct links are allowed. He proposes a B&B algorithm where lagrangean relaxation is used for obtaining the lower bounds. Aykin (1995a) analyzes the hub location problem with fixed costs for given  $p$ . Two hubbing policies are compared. The first one is called the non-strict hubbing policy and, he formulates this policy and solves it to optimality by enumeration. Also a greedy-interchange heuristic for this policy is proposed. The second policy is called the strict hubbing policy.

In Klincewicz (1996) a set of potential hubs is used for determining the hub locations and a dual-ascent and dual adjustment techniques based B&B algorithm is tested.

Abdinnour-Helm and Venkataramanan (1998) propose a quadratic integer formulation for the uncapacitated single allocation hub location problem with fixed costs making good use of the multicommodity flows in networks. Their formulation is denoted by the name MCUHP. They propose a B&B method with the lower bounds resulted from the structure of the network in order to get

the optimal solution. In addition, they develop a genetic algorithm for that problem.

Abdinnour-Helm (1998) proposes a new hybrid heuristic called GATS which is a hybrid of genetic algorithms (GA) and tabu search (TS). First, the number and the location of the hubs are determined by the genetic algorithm and then, each node is allocated to the nearest hub. They start the tabu search with this solution and the hybrid of the tabu search and genetic algorithm results with better solutions than the pure genetic algorithm.

Two new formulations by modifying the mixed integer formulations of the p-hub median problem are presented in the study of Ernst and Krishnamoorthy (1999). A simulated annealing based heuristic and a random descent based heuristic are provided for the problem. They test their methodology on the AP data set. As a result, they see that both heuristics are quite efficient and, the random descent heuristic to be more efficient for small and medium sized problems. The simulated annealing heuristic is also found to be more efficient for large problem.

Ebery et al. (2000) survey the capacitated multiple allocation hub location problem with fixed costs. They propose a formulation similar to the formulation of Ernst and Krishnamoorthy (1998a) for the multiple-allocation p-hub median problem. They propose an LP based B&B technique in which an upper bound from a shortest path based heuristic is integrated. The results using the CAB and the AP data sets show that it is possible to solve large problems with their new formulations in a reasonable amount of time.

Mayer and Wagner (2002) develop a method called “Hub Locater” for the multiple allocation uncapacitated hub location problem which is based on a B&B technique. Since The Hub Locater obtains tight lower bounds for the problem, this formulation results in reduced computational effort. The comparison of the Hub Locater with the B&B algorithm of Klincewicz (1996)

and with optimum or near optimum solutions of CPLEX shows that the hub locater is superior to the B&B algorithm of Klincewicz (1996).

Marianov and Serra (2002) present a formulation for the multiple allocation hub location problem with fixed costs that takes into account the congestion at the hubs. Their model has two versions. In the first version, the number of runways to open a hub is given, while in the second version this number is a decision variable of the model. Their model transforms the probabilistic constraint about the congestion in a hub to a deterministic linear constraint. They also propose a tabu search based heuristic to solve the problem.

Sasaki and Fukushima (2003) study the multiple allocation capacitated 1-stop hub location problem with fixed costs where they put constraints on both hubs and arcs. They propose a Lagrangean relaxation based B&B algorithm for their formulation.

Boland et al. (2004) develop some preprocessing techniques and some tightening constraints with the help of the properties of the optimal solutions. The aim of their study is to get some improvements of the linear relaxations of the mixed integer formulations. Some flow-cover constraints are also employed in their study to decrease the computation times.

Mari'n (2005a) uses some of the ideas presented in Mari'n et al. (2006) to reduce the size of the problem for the capacitated multiple allocation hub location problem with fixed. The computational experience on the AP data set shows that medium size problems can be solved more efficiently with this new formulation than the previous formulations. Mari'n (2005b) develops a relax-and-cut algorithm for the multiple allocation uncapacitated hub location problem with fixed costs by applying some polyhedral properties of the set-packing problem. Computational study is carried out using the AP data set and it is seen that the instances are solved to optimality with low computational effort by relax-and-cut algorithm. Mari'n et al. (2006) relax the assumption of

the costs satisfying the triangle inequality and present a formulation for the uncapacitated multiple allocation hub location problem with fixed costs. They use some polyhedral results to tighten the constraints and decrease the number of them.

Topçuoğlu et al. (2003) propose a GA-based heuristic performs better than the GATS heuristic of Abdinour-Helm (1998). Later, Cunha and Silva (2007) develop a hybrid of GA and simulated annealing heuristic for the same problem instance. In their problem, the discount factor  $\alpha$  may vary with the total amount of load between the hubs. For this problem, Chen (2007) proposes another hybrid of simulated annealing heuristic, tabu search and improvement procedures.

For the uncapacitated multiple allocation problem, Ca'novas et al. (2007) carry out a dual-ascent technique based heuristic within a B&B algorithm. They obtain the best solutions for the uncapacitated multiple allocation hub location problem with fixed costs according to Alumur and Kara (2007).

Costa et al. (2007) propose a bi-criteria approach for the capacitated problem. Rather than imposing capacity constraints for the hubs, they introduce another objective function for the processing time in the hubs. They consider two formulations called BSAHLP-1 and BSAHLP-2. Both formulations have minimizing the total transportation cost and fixed cost of locating hubs as the first objective function. The second objective function in BSAHLP-1 is to minimize the total processing time in the hubs and the second objective function in BSAHLP-2 is to minimize the maximum processing time among the hubs. They propose an iterative solution procedure to find the non-dominated solutions.

Camargo et al. (2008) present a Benders decomposition based algorithm. Their algorithm is based on the formulation of Hamacher et al. (2004). In fact, they implement three variants of the Benders decomposition. In order to test these

formulations, they use the AP data set and the CAB data set with minor modifications. Camargo et al. (2008) note that, instances of large sizes which are solved by the Benders decomposition have not been solved to optimality until that time.

Silva and Cunha (2009) propose an integrated tabu search heuristic with two-stages and three different multi-start tabu search heuristic. They perform computational studies using the CAB data set and the AP data set as well as other problem instances.

The Table 2.3 summarizes the literature on the hub location problem with fixed costs.

### 2.1.3 The p-Hub Center Problem

The p-hub center problem is analogous to the p-center problem which is min-max type one to minimize the adverse effects of the worst case. There are  $n$  nodes and the demand between each origin-destination pair with the number of hubs to be opened,  $p$ , are given. The aim is to locate the hubs and allocate the non-hub nodes to these hubs with the objective of minimizing the maximum route length or maximum cost. Center type problem formulations are important both because of applications and worst case scenarios, like emergency service facilities locations or maximum travel times (Campbell, 1994b).

Campbell (1994b) first formulates and discusses the p-hub center problem in the literature. He examines the origin-destination path by treating the links in a path; origin-to-hub, hub-to-hub and hub-to-destination links; separately. According to this separation, he studies three types of p-hub center problem in terms of the link considered. In the first type of the p-hub center problem, the maximum cost (length) from a origin node to a destination node is minimized. A second type is minimizing the maximum cost (length) of any of the three single links mentioned above. In the third type of the problem, which is called vertex centers, the maximum cost (length) for a link between a hub and a non-hub node is taken into account. Campbell presents the first formulations of single and multiple allocation versions of all these types of problems.

Kara and Tansel (2000) study the single allocation p-hub center problem of Campbell's first type problem which has the objective of minimizing the maximum cost (length) of any origin-destination pair. They first give a combinatorial formulation of the problem and prove that it is NP-hard.

Kara and Tansel (2001) focus on models that are especially suitable for cargo companies. They propose new models for the latest arrival hub location problem. In those models, the time spent at the hubs called the transient times is included, since these times are significant for cargo delivery systems. They

propose single and multiple allocation versions of minisum, minimax and covering type latest arrival hub location problem. They focus on the single allocation version of minimax type latest arrival hub location problem and show that this problem is NP-Hard. Later, Wagner (2004a) shows that the critical paths of the minimax type latest arrival hub location problem and of the p-hub center problem that ignores transient times are the same, if the objective functions depend just on the maximum travel time. However, the minisum type latest arrival problem is different. He also shows that the minimax type latest arrival hub location problem outperforms the p-hub center problem in terms of CPU time required.

Pamuk and Sepil (2001) propose a single exchange heuristic and superimpose a tabu search to prevent being trapped by the local optima. Three intuitively appealing heuristics are used for the locations of the initial hubs. They study the p-hub center problem with single allocation and strict hubbing policies.

Ernst et al. (2002a) develop a new formulation for the single allocation p-hub center problem which has more variables but fewer constraints than the formulation of Kara and Tansel (2000). When Ernst et al. (2002a) compare the two formulations, they see that their formulation requires less CPU time than the formulation of Kara and Tansel (2000). Ernst et al. (2000a) also provide two new formulations for the multiple allocation p-hub center problem and prove the NP-hardness of it. They develop a heuristic method for the single and multiple allocation of the p-hub center problems. Ernst et al. (2002b) focus on the allocation subproblem of the single allocation p-hub center problem for fixed hubs. They present linear programming formulations for this subproblem and prove the NP-Hardness of it. In addition, they propose five heuristics for the allocation subproblem and analyze the worst case performances of the heuristics.

Hamacher and Meyer (2006) propose a procedure to solve the uncapacitated single allocation p-hub center problem with a binary search algorithm

BS(HcoP) which is based on the inverse relationship of the p-hub center problem and the hub covering problem . The feasibility polyhedron and many classes of facet defining valid inequalities are analyzed. The two most efficient hub covering formulations and the radius formulation of USApHCP are compared with each other. Although all algorithms find the optimal solution, BS(HcoP) performs better mostly with respect to the computational time.

Kratica and Stanimirovic' (2006) propose a genetic algorithm with binary coding for the uncapacitated multiple allocation p-hub center problem. They construct and implement problem-specific genetic operators in their genetic algorithm. The computational studies on the CAB and the AP data sets indicate that their genetic algorithm obtains all solutions that have been proved to be optimal in a reasonable amount of time.

Juette et al. (2007) study the polyhedral analysis of the uncapacitated single allocation p-hub center problem. The analysis is based on a radius formulation of Ernst et al. (2000a) and they show which of the valid inequalities in the formulation are facet-defining and which present non-elementary classes of facets for which they propose separation problems.

Yaman et al. (2005) analyze the latest arrival hub location problem with stopovers and they include the transient times, the time spent for unloading, sorting and loading at hubs in their model. The model is strengthened with some valid inequalities. The model is verified with CAB data set and tested with a data set constructed from the Turkish map.

Gavriliouk (2008) considers aggregation heuristic procedures for the hub location problems and calculates bounds for errors from such heuristics. The computational performance of the heuristic is tested on the AP data set and a randomly generated, and it is shown that the heuristic results in shorter times than solving in CPLEX.

Meyer et al. (2008) present an exact 2-phase algorithm. In the first phase, a set of potential optimal hub locations is computed with a shortest path based B&B algorithm and in the second phase, allocation phase, the optimal allocations are computed accordingly. They also develop an ant colony optimization heuristic for the upper bound needed for the B&B. The solution approach is shown to be significantly faster than MIP solver and CPLEX using AP data set and a newly generated data set. They are able to provide exact solutions to the single allocation p-hub center problems up to 400 nodes.

Sim et al. (2009) present the stochastic p-hub center problem with chance constraints. He proposes a two stage heuristic approach. In the first stage of the heuristic, an initial feasible solution is generated by a radial heuristic. And then, in the second stage of the heuristic, the initial solution is improved by the one-opt best-improvement heuristic which is proposed by Teitz and Bart (1968). Computational results show that in many this heuristic ends up with better objective function values than that of the Teitz-Bart heuristic with randomized initialization.

Ernst et al. (2009) prove both the uncapacitated single and multiple allocation p-hub center problems are NP-Hard. Even the single allocation sub-problem is shown to be NP-Hard. They formulate both problems and propose a shortest path based B&B approach for the multiple allocation problem. The numerical experiments with CAB and AP data sets show that their new formulation for USApHCP is superior to Kara and Tansel in terms of computational time. Also the shortest path based B&B method is shown to be extremely efficient for solving UMApHCP.

In Table 2.4, we summarize the literature on the p-hub center problem.

### 2.1.4 Hub Covering Problems

In the hub covering problems, there are  $n$  nodes and the flow between each pair of nodes is given. In the hub covering problem the aim is to find the minimum number of hubs (which is essential to find the minimum cost of establishing hubs) in order to satisfy a given service level.

In the set covering hub problem, the aim is to determine the number and places of hubs and the route an origin node and a destination node (in other words, the assignment of the remaining nodes to the hubs) so that all demand is covered and the total fixed cost of the hubs is minimized. In the maximal covering hub problem, the number of hubs to be opened is given as  $p$  and the objective is to maximize the covered demand.

Campbell (1994b) first defines and formulates the hub covering problems. He defines three coverage criteria. The first criterion is that the cost of the complete path from node  $i$  to node  $j$  via the hubs  $k$  and  $m$  should not exceed a predetermined value then the origin-destination pair  $(i,j)$  is assigned to hubs  $k$  and  $m$ . According to the second coverage criterion, the origin-destination pair  $(i,j)$  is covered by hubs  $k$  and  $m$  if the cost for each link (non-hub nodes to hubs or hub to hub links) does not exceed a predetermined value. According to the third coverage criterion, the origin destination pair  $(i,j)$  is covered by hubs  $k$  and  $m$  if the cost of each of the origin-hub and hub-destination links does not exceed separately the specified values.

Kara and Tansel (2003) prove the NP-hardness of the single allocation hub-set covering problem. They provide three different linearizations of the quadratic formulation of Campbell (1994b) and propose a new formulation of the problem and a linearized version of it called HC-Lin. The comparison of these four linearizations shows that the performance of the linearization of their model is superior to the performances of the linearizations of Campbell (1994b).

Wagner (2004b) reduces the formulation of Kara and Tansel (2003) with preprocessing techniques, thus reduces the number of variables and constraints of formulation with preprocessing techniques. Furthermore, by the aggregating some of the constraints, he improves his formulations.

Ernst et al. (2005) propose a new formulation based on a concept of cover radius  $\beta$  which is similar to the p-hub center problem formulation of Ernst et al. (2002a). Also, two new formulations and an enumeration based algorithm are proposed for the multiple allocation hub set covering problem in their study.

Hamacher and Meyer (2006) analyze the facet-defining valid inequalities for the hub set covering problem. They propose a procedure for solving the uncapacitated single allocation p-hub center problem by solving the hub covering problem for a given  $\beta$  combined with binary search.

Sim (2007) introduces the hub covering flow problem motivated by the air travel industry considering the amount of flow at the arcs as well. For the coverage criterion, the distance of each of the links between the hub nodes and non-hub nodes are considered. Each non-hub node is allocated to a single hub. He proposes two formulations. In the first formulation, coverage requirements are included in a constraint. In the second formulation, coverage requirements are included in the objective. In both formulations, only one aircraft-type is assumed to operate out of a hub. He also performs computational tests and sensitivity analysis for the hub covering flow problem using the AP data set. Sim (2007) states that alternative solution approaches should be proposed for the hub covering flow problem other than using commercial solvers especially for large problems.

Tan and Kara (2007) study the latest arrival hub covering problem for cargo delivery systems. In this problem, the departure from a hub does not occur until the latest arrival to the hub from the nodes that it serves or from the other hubs. So these departure times are in the model and a linear model called Latest Cover is written. Then, two variations of this model called Latest Cover-1 and Latest Cover-2 are presented. In Latest Cover-2, weights for each possible hub location are included in the model. In latest Cover-2, a tight service level for some cities and an extensive service level for the rest are imposed in the model. Tan and Kara (2007) test their models on the 81-node Turkish postal network

and also on the CAB data set. Furthermore, they incorporate a limit on the driving time of a driver as a result of a legislative requirement and improved the CPU time of the models, but the number of opened hubs increased.

Alumur and Kara (2007) focus on a single allocation hub covering problem for cargo applications in Turkey. They relax the complete hub network assumption and a hub may not be directly linked to all other hubs in their model. However, the number of hubs that can be visited on a route is limited by three, because of safety reasons and the geographical structure of Turkey. The possible waiting times at the hubs are taken into consideration by their model. Each demand from an origin to a destination should be satisfied within a time limit. Firstly, a nonlinear MIP called 3-stop-0 is written to find the location of the hubs, allocation of the nodes to the located hubs and ready time of each hub in order to minimize the fixed hub costs and hub-to-hub link costs. Then a linearized version of it called 3-stop is written. Alumur and Kara (2007) solve their linear model by CPLEX 8.1 using data from the Turkish network and the CAB data set. They use the tightest possible time limits in their test data. In spite of this, their model gives optimal solutions in reasonable CPU times with both the Turkish network data and the CAB data set. They observe that the solutions are usually insensitive to the hub-to-hub link costs, although the low link costs require less CPU time. Another observation of them is that their model produces incomplete hub networks in most of the cases despite using the tightest possible time limits in their test data.

Wagner (2007) proposes a formulation for the single allocation hub set covering problem for the case where the discount factor between any two hubs is independent of the quantity transported between them. In this formulation, he uses some preprocessing techniques to determine the valid and incompatible assignments. In this way, he eliminates some assignments and decreases the number of variables and constraints compared to the formulation called HC-Lin of Kara and Tansel (2003). This formulation is called SAQI-W1. Then, he

obtains the formulation called SAQI-W2 of the same problem by aggregating some constraints of SAQI-W1. Nets, a formulation of the single allocation hub set covering problem for the case where the discount factor between any two hubs is dependent of the quantity transported between them is given by Wagner (2007). This formulation is called SAQD-W. Wagner (2007) also proposes a formulation for the multiple allocation case of the same problem for the case where the discount factor between any two hubs is independent of the quantity transported between them. In this formulation, the number of constraints and variables are reduced compared to the formulation of Campbell (1994b) for the same problem with the help of using valid route sets. This formulation is called MAQI-W.

Calik et al. (2009), in their study, allow their model to have incomplete networks in the hub level and impose time restrictions on the delivery times. They develop a linear MIP for the single allocation hub covering problem with these constraints and configuration, and propose a metaheuristic based on the tabu search. The tabu search based heuristic is tested using data from the Turkish network and also the CAB data set.

Alumur et al. (2009) focus on the design of single allocation incomplete hub networks. They relax the complete hub network assumption and a hub may not be directly linked to all other hubs in their model like in Calik et al. (2009). They give an  $O(n^3)$  formulation for the problem. They also propose four valid inequalities to increase the exact solution potential. Also, Alumur et al. (2009) propose that they are able to solve the largest instances of incomplete hub networks to optimality in the literature up to that time. Alumur et al. (2009) also provide  $O(n^3)$  formulations for the single allocation incomplete p-hub median problem, hub location problem with fixed costs and p-hub center problem.

Qu and Weng (2008) focus on the multiple allocation hub maximal covering problem introduced by Campbell (1994b). The objective of the hub maximal

covering problem is to maximize the covered demand while determining the places of hubs and the route of each demand denoted by an origin node and a destination node. They provide a new model for this problem and propose an evolutionary approach based on Path Relinking in order to solve it.

The Table 2.5 summarizes the hub covering problem literature.

### **2.1.5 Other Hub Location Studies**

Kuby and Gray (1993) study the hub network design problem with stopovers and feeders. In the model, multiple node visits are allowed before arriving at a hub and after departing from a hub and each such visit is called a stopover.

Considering the models for the capacitated airline networks in their study, Jaillet et al. (1996) do not force hubs to occur in their solutions; only when it is found to be cost efficient, the model results in a network with hubs.

Unlike most of the studies, O'Kelly and Bryan (1998) adopt a non-linear cost function which allows costs to change with the traffic on hub-to-hub links.. Then Bryan (1998) extends the formulation presented in O'Kelly and Bryan (1998) by adding capacities and flow thresholds for minimum flows on hub-to-hub links. She also extends the flow dependent discount factor to all links in the network, not just to hub-to-hub links. Horner and O'Kelly (2001) state that economies of scale can be seen on all links in a network and so they apply a piecewise-linear concave cost function like Bryan (1998).

Marianov et al (1998) propose a model called the hub location competitive model (HuLC). In that model, if the cost of satisfying the demand of an origin-destination pair for a firm is less than the cost of competitors, that demand is completely captured by that firm. The aim of the model is to maximize the sum of the captured demand for a firm. The number of hubs to be opened is given as  $p$  and the location of hubs, the flows that are captured and the route of the captured origin-destination flows are determined in the model. Then the model is refined for the case where the number of hubs to be opened is not pre-specified. Another modification is done for the case where relocation and/or addition of hubs are possible. A further modification is done for the case where capture of some fraction of a demand between two nodes is possible. A tabu search heuristic is proposed for the solution of the model and it is evaluated

using randomly generated data as well as the AP data set. The heuristic obtains the optimal results in all test runs.

Drezner and Drezner (2001) propose a model for the airline hub selection problem. In their model,  $p$  numbers of hubs are opened in order to minimize the total miles travelled by passengers. Passengers use one hub on the way to their destination. They test their model by changing various parameters and comment on the results.

Nickel et al. (2001) present a network design problem for the urban public transportation networks. They relax the complete network assumption and impose a fixed cost for locating hub arcs in their model.

Sung and Jin (2001) partition the nodes into clusters. For each cluster, one node in the cluster should be determined as a hub for that cluster. Direct links between nodes within the same cluster are allowed in the model and the aim is to minimize the total fixed cost of locating hubs and the total transportation cost. Later, Wagner (2007) shows that the model of Sung and Jin (2001) is NP-hard and he proposes a new mixed integer programming formulation for that problem. There are fewer variables in the formulation of Wagner (2007) than the formulation of Sung and Jin (2001). He also proposes a constraint programming approach and some preprocessing techniques for using MIP solvers for that problem.

Klincewicz (2002) focuses on a generalization of the multiple allocation p-hub median problem where the unit cost of transportation between two hubs is dependent on the amount transported between them. Klincewicz (2002) proposes an enumeration method, a tabu search heuristic and a greedy random adaptive search procedure (GRASP) for this problem. He evaluates his solution procedures on the CAB data set and shows that the optimal hub locations depend on the cost function used.

O’Kelly and Bryan (2002) examine the optimal locations of the interactive facilities. They analyze the behavior of solutions to several alternative models.

Podnar et al. (2002) propose a network design problem in which hubs are not located. Instead, they determine the flows on the links and impose reduction on the unit transportation costs by a factor  $\alpha$ , for the flows larger than a specified threshold value on a link.

Zapfel and Wasner (2002) analyze a hybrid hub-and-spoke system for a single product. The places of the hub and the non-hub nodes are fixed. There are two types of trucks with different capacities. First, they focus on the line haul problem. In this problem, both direct transports between non-hub nodes that do not use hubs and transports between non-hub nodes that use hubs are allowed. The aim is to determine the number of the two types of trucks used and the quantity transported between any two non-hubs and hubs and non-hubs, so that the total transportation cost is minimized. For the solution, a partial enumeration heuristic is developed that first decreases the number of possible solutions using rules of the expert system and then does enumeration among the remaining possibilities. Then, combined line haul and pickup/delivery problem is formulated that also takes the pickup and delivery tours between non-hub nodes and customers into consideration.

Lin et al. (2003) study the economic effects of hub and spoke networks with center to center directs. They model the hub-and-spoke network with center directs in the paths and their model determines the fleet sizes, fleet routes and freight paths so that the total costs are minimized while the service restrictions and operational restrictions are satisfied. They solve their model using CPLEX and compare their results with the Federal Express AsiaOne express network.

Carello et al. (2004) focus on the hub location problem in telecommunications network design. There are some access nodes that represent origins and destinations of traffic that are not connected directly. Transit nodes (hubs) are

chosen among some candidate nodes and the hubs are fully connected. Hubs are capacitated. The problem is to select the number and location of hubs and the allocation of non-hub nodes to hubs in order to minimize the total cost. Cost components are the fixed cost of opening hubs and the installation cost of the capacity on the edges needed. Three different metaheuristics are developed for this problem, which are tabu search, iterated local search and random multistart. The most promising metaheuristic is found to be the tabu search as a result of the computational experiments.

Campbell et al. (2005a) present a model in which the locations of the hub arcs are determined. Campbell et al. (2005b) present integer programming formulations for the four different cases of the hub arc location problem and two optimal solution algorithms for them, one being the enumeration-based optimal algorithm and the other using the commercial MILP solver CPLEX 6.6.

In Kimms (2005) all the links in the network are assumed to have the possibility of having economies of scale like Bryan (1998) and Horner and O’Kelly (2001). His model has a piecewise-linear concave cost function and fixed cost for the usage of each link.

Yaman (2005) provides polyhedral analysis for the problem called the uncapacitated hub location problem with modular arc capacities. The problem is to locate the hubs, assign non-hub nodes to hubs and install capacities on the arcs so that the total cost of installing the hubs and capacity units on the arcs are minimized.

Yaman and Carello (2005) consider the problem called the capacitated hub location problem with modular link capacities. The hubs have a capacity which represents the maximum amount of traffic that can be routed through the hub. Integer-valued capacity units are installed on the edges. The problem is to locate the hubs, assign each non-hub node to a hub and install capacities on the

edges so that total hub and link costs are minimized and capacity constraints are satisfied. They formulate this problem as a quadratic mixed integer program and then linearize it. In order to solve the problem, an exact branch-and-cut algorithm and a two-level local search metaheuristic are developed. The branch-and-cut algorithm taking the upper bound from the two-level local search metaheuristic and the combination of the two solution approaches are applied on a number of test instances.

Sim (2007) addresses the two-stage stochastic p-hub center problem for the communication networks. In the first-stage, the best locations for  $p$  hubs in the network are found and in the second stage, each node is assigned to only one of the given hubs in order to minimize the longest connection path in the network. He gives a formulation of the problem and uses a radial heuristic to solve the first stage and CPLEX to solve the second stage. He also proposes a simulated annealing heuristic to solve large problems. He performs computational tests on the CAB and the AP data sets for these solution approaches.

In this study we also address the p-hub center problem with stochastic service level constraints. Our study differs from theirs in two aspects:

- Objective function:
  - Sim (2007) defines the objective function as the minimization of the service level  $\beta$  (maximum travel time that should be satisfied with probability  $\gamma$ )
  - We define the objective function as the minimization of the maximum weighted travel time less than a given service level  $\beta$  that should be satisfied with probability  $\gamma$  at least for specified node pairs.

- Solution approach:
  - Sim proposes a 2-stage approach in which the two decisions, location and allocation, are made sequentially; first location of hubs, then allocation of non-hubs to hubs.
  - We solve these two problems simultaneously using a genetic algorithm.

## **CHAPTER 3**

### **3. MATHEMATICAL MODELING OF THE p-HUB CENTER PROBLEM WITH SERVICE LEVEL CONSTRAINTS**

In this chapter, we give the general description of the p-hub center problem and we define our problem characteristics with the assumptions in this study, followed with the related mathematical model of our formulation.

#### **3.1 The p-Hub Center Problem**

Airline systems, cargo delivery systems and telecommunication networks are some application areas of hub location problems. We mainly focus on the cargo delivery system and the Turkish network of towns in this study.

p-hub median problem, whose objective is the minimization of the total cost, is exclusively focused on among the existing literature (Kara and Tansel, 2000). Although the minimization of the total cost is a worthy objective, the minimax criterion is still very crucial in terms of minimizing the worst delivery time in cargo delivery systems, especially for delivery of perishable and time-sensitive items. In this competitive environment, cargo delivery companies need to offer reliable deliveries and offer guarantees on the delivery times. The companies can decide on what service guarantees they can offer according to their network designs. Among the hub location problems, the p-hub center problem is the most suited model in finding out the maximum time limit to be given to the customers for the deliveries.

The p-hub center problem, in general, has the following characteristics:

- There are  $n$  nodes in the network which are the origin-destination points,
- The distance (or travel time) between the nodes are given and satisfies the triangular inequality,
- The hub level network is complete,
- The number of hubs to be located is given as  $p$ ,
- There is a discount on the hub-to-hub links incorporated with a discount factor  $\alpha$ .

The decisions to be made are the locations of the hubs and the allocation of the non-hub nodes to the hubs with the objective of minimizing the maximum cost or the maximum travel time of the network.

p-hub center problem, having components of both location and allocation problems and both uncapacitated multiple and single allocation p-hub center problems, are proven to be NP-Hard (Ernst et al., 2009).

### **3.2 The Characteristics of the Problem Environment**

Besides the general definition for the p-hub center problems above, we define our problem environment characteristics as follows:

Characteristics of the p-Hub Center Environment:

- The travel time is more crucial than the cost of the delivery, for the cargo delivery firms, hence the objective function is to minimize the maximum travel time of the paths between the origin-destination pairs.
- Cargo firms take into account mainly the amount of flows between the node pairs in decision making processes. In Turkey, although it may not be a long travel time between any origin-destination, it is highly likely that only a single delivery in a week occurs because of the low volume

of flow. Using only the travel time means giving equal importance for the node pairs having the same travel time. However, when we have two different node pairs having the same travel time, the one with the higher volume of flow will be more crucial for the cargo delivery firms. In order to reflect the effect of the flow density on the solution, the travel times between the node pairs are weighted with the flow weight among of the node pairs, as an attempt to give more importance to the nodes with high interactions.

- Single allocation of the nodes to the hubs is assumed; moreover no direct transportation between the non-hub nodes is allowed. As a result every node should be assigned to one and only one hub.
- In the study, there exist no capacity restrictions for the hubs and the arcs. So there is no limit on the number of nodes that can be assigned to a hub.
- In real life, the problem environment of the hub location issues is not deterministic as assumed in the mathematical models. The flow between the nodes may vary as a result of special days or events, like Christmas or the travel time between the nodes may vary because of the weather conditions. For representing the consequences of the variability in the problem environment, we have used the idea of stochastic service level constraints of Sim et al. (2009). As in the study of Sim et al. (2009), we try to introduce the variability in travel times only, since we deal with the travel times in the objective function when designing the hub network of our study and since we do not have any capacity restrictions. The travel times among the nodes are assumed to be uncertain and distributed with the normal distribution and the real travel times are taken as the mean of the travel times.
- Guaranteed overnight delivery has become an important condition for the high market shares. Customers want to have rapid and reliable deliveries. However it is not possible to guarantee overnight delivery

for all the node pairs. First of all, the travel time among the node pairs should be in a reasonable limit. Moreover, to be cost effective for the firm, the node pairs should have an interaction in between higher than a threshold level. For observing the resulting effects, we define a service level target, which can be 24-hour for overnight delivery case, to be achieved. As mentioned, this target cannot be reasonable for all node pairs because of both physical and financial reasons. We also define,  $F_{ij}$ , a lower limit on the flow between a non-hub-node pair  $i$  and  $j$ , and  $T_{ij}$ , an upper limit on the mean travel time between the non-hub node pair  $i$  and  $j$  that identifies the targeted service level applicability. Sim et al. (2009), in their study, try to find the minimum travel-time guarantee for the whole network with a predetermined level of probability with chance constraints. Instead of targeting to find a travel-time guarantee to the whole network, we determine a travel time guarantee in advance for certain node pairs, and try to find the resulting network that achieves the predetermined travel time guarantee for the predetermined node pairs  $i$  and  $j$  by the limits  $F_{ij}$  on the flow and  $T_{ij}$  on the mean travel time.

- A restriction on the maximum travel times between a non-hub node and a hub node is imposed in our model as in Tan and Kara (2007), which is a reflection of a real life restriction on the driving time of a commercial driver. However, this restriction is not imposed on the links between the hub nodes, since larger special trucks with more than one driver are used on these hub-hub links.

### 3.3 Mathematical Modeling of the Problem

We develop a linear integer programming model for our p-hub center problem. We have  $N$  nodes and aim to locate  $p$  number of hubs among these  $N$  nodes with the objective of minimizing the maximum weighted travel time between

the node pairs via the hubs. By using the weighted travel times in our objective function, we try to give more importance to the node pairs with larger flows. In Figure 3.1, we have a 1-hub network with 5 nodes. The links between the nodes A-D and C-B via hub E have travel time of 10 hours; however the flow between A and D is 100 units, while it is 10 units between C and B. It is obvious that for a cargo firm transferring 100 units of flow within 10 hours is much more important than transferring 10 units within 10 hours.

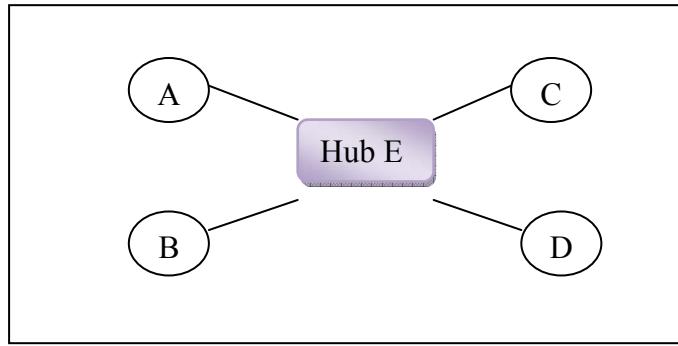

Figure 3.1 One-Hub Network with 5 Nodes

The center type location problems, as a course of their nature, may have alternative optimal solutions (Sim et al, 2009). When only the weighted travel times are used in the objective function without any constraints on the assignment of the nodes, only the maximum weighted travel time in the network becomes important. As a result other, locations and assignments do affect the solution in the model. However, with the service level constraint imposed on the specified nodes, we try to control the assignment of other nodes with high interactions and maintain a reasonable travel time between hub pairs. Moreover, the restriction on the maximum travel times on the node-hub links also eliminates some of the alternative solutions of the pure p-hub center problem and contributes to the enhancement of the resulting network structure.

We first describe the sets, parameters and decision variables, and then present the integer model for our p-hub center problem with service level constraints.

### Sets

$I$  set of nodes

$K$  potential hub nodes

### Parameters

$F_{ij}$  amount of flow from origin node  $i$  to destination node  $j$

$W_{ij}$  weight of the flow between node  $i$  and node  $j$ : ratio of the flow between node  $i$  and node  $j$  to the total flow on the network

$T_{ij}$  travel time (minute) on the link from node  $i$  to node  $j$  and  $T_{ij} \sim N(t_{ij}, \sigma_{ij}^2)$

$t_{ij}$  mean travel time (minute) on the link from node  $i$  to node  $j$

$\sigma_{ij}$  standard deviation of the travel time on the link from node  $i$  to node  $j$

$p$  number of hubs to be located

$\alpha$  discount factor for the inter hub transportation

$\beta$  targeted service level between the specified nodes

$\gamma$  target service level probability

$L$  restriction on the maximum travel time between a non-hub node and a hub

$Q$  lower limit on the flow between any non-hub nodes for the service level constraint to be considered.

$H$  upper limit on the mean travel time defined for any two origin-destination nodes for the service level constraints to be considered.

### Decision Variables

$$X_{ijkm} = \begin{cases} 1, & \text{if there is a path from origin node } i \text{ to destination node } j \text{ via the hubs } k \text{ and } m \\ 0, & \text{otherwise} \end{cases}$$

$$Y_{ik} = \begin{cases} 1, & \text{if node } i \text{ is assigned to hub } k \\ 0, & \text{otherwise} \end{cases}$$

$$Y_{kk} = \begin{cases} 1, & \text{if hub } k \text{ is opened} \\ 0, & \text{otherwise} \end{cases}$$

Z= objective function value

### Model

Min Z

Subject to

$$Z \geq W_{ij} \{ X_{ijkm} (t_{ik} + \alpha t_{km} + t_{jm}) \}, \quad \forall i, j \in I \text{ and } \forall k, m \in K \quad (3.1)$$

$$P\{X_{ijkm} (T_{ik} + \alpha T_{km} + T_{jm}) \leq \beta\} \geq \gamma,$$

$$\forall (i, j, k, m) \text{ for } F_{ij} + F_{ji} \geq Q \text{ and for } t_{ij} \leq H \quad (3.2)$$

$$t_{ik} Y_{ik} \leq L, \quad \forall i \in I \text{ and } \forall k \in K \quad (3.3)$$

$$\sum_k Y_{ik} = 1, \quad \forall i \in I \quad (3.4)$$

$$\sum_k Y_{kk} = p, \quad \forall k \in K \quad (3.5)$$

$$Y_{ik} \leq Y_{kk}, \quad \forall i \in I \text{ and } \forall k \in K \quad (3.6)$$

$$X_{ijkm} \leq Y_{ik} + Y_{jm} - 1, \quad \forall i, j \in I \text{ and } \forall k, m \in K \quad (3.7)$$

$$\sum_m \sum_k X_{ijkm} = 1, \quad \forall i, j \in I \text{ and } \forall k, m \in K \quad (3.8)$$

$$X_{ijkm}, Y_{ik}, \in \{0, 1\}, \quad \forall i \in I \text{ and } \forall k \in K \quad (3.9)$$

The constraint (3.1) satisfies the minimization of the maximum of the weighted travel times of the resulting network in the objective function. The travel times include the time for a complete link from a non-hub-node to another non-hub-node that constitutes all the links from a non-hub node (i) to a first hub, from the first hub (k) to the second hub (m) and from the second hub (m) to a non-hub node (j). The constant  $\alpha$  in the equation corresponds to the discount on the travel time between the hub nodes k and m. Since in our study the travel times are uncertain, we use the mean values of the related times in the objective function. It can also be possible to construct this constraint such that instead of using the mean travel times, random values can be used. However, since we do not have distribution of the travel times of the network, we use the travel time data of the network as the mean travel times and calculate the related standard deviations through constant coefficient of variations (CV). This means that, whether using the mean travel times or random travel times for the objective function does not change the path that has the maximum weighted travel time. So, we conclude to use the mean travel times for the objective function calculations.

Constraint (3.2) requires that, for the non-hub-node pairs  $i-j$  that have a total flow greater than  $Q$  and that have a mean travel time lower than  $H$ ; the probability of the resulting travel time from node  $i$  to node  $j$  via hubs  $k$  and  $m$  to be smaller than or equal to  $\beta$ , should be greater than or equal to the target service level probability  $\gamma$ . As mentioned before, the travel times are assumed

to be normally distributed by  $T_{ij} \sim N(t_{ij}, \sigma_{ij}^2)$ ; which results in  $(T_{ik} + \alpha T_{km} + T_{jm}) \sim N(t_{ik} + \alpha t_{km} + t_{jm}, (\sigma_{ik}^2 + \alpha^2 \sigma_{km}^2 + \sigma_{jm}^2))$ . The constraint (3.2) can then be expressed as;

$\beta \geq X_{ijkm}(t_{ik} + \alpha t_{km} + t_{jm} + z_\gamma \sqrt{\sigma_{ik}^2 + \alpha^2 \sigma_{km}^2 + \sigma_{jm}^2})$  where  $z_\gamma$  is the z-value corresponding to the probability  $\gamma$ . This equation is used to substitute the constraint (3.2). We use the real travel times as the mean travel times and calculate the corresponding standard deviations from these mean travel times using the specified  $CV$  value.

Constraint (3.3) assures that the travel time between a non-hub node and a hub node does not exceed the specified restriction  $L$  and this constraint reflects the real life restriction on the maximum traveling time of a commercial driver.

Constraint (3.4) is the single-assignment constraint that guarantees the assignment of every non-hub-node to exactly one hub.

Constraint (3.5) guarantees that  $p$ - given as a parameter in the model- number of hubs are opened in the resulting network.

Constraint (3.6) prevents the assignment of a non-hub-node to a location where no hub is located.

Constraint (3.7) satisfies the existence of a path between an origin node and a destination node over two hubs, via only the hubs which the nodes are assigned to.

Constraint (3.8) guarantees a single path between an origin node and a destination node over two hubs.

Constraint (3.9) defines the variable types in the model as binary. Actually  $X_{ijkm} \in \{0, 1\}$  constraint is satisfied in the model implicitly because of the single allocation requirement with no capacity restrictions.

### 3.4 Complexity of the Model

The  $p$ -hub center problems, both single and multiple allocation are proved to be NP-hard. Especially for the large problems, the number of possible location and allocation alternatives becomes very high. For instance, for an  $n$ -node network with  $p$  hubs; the number of possible hub locations is:

$$\binom{n}{p} = \frac{n!}{p!(n-p)!}$$

Moreover, for each hub location alternative, the model has  $(n - p)^p$  allocation alternatives. Consequently, the number of total location and allocation alternatives for an  $n$ -node and  $p$ -hub hub center problem is:

$$\frac{n!}{p!(n-p)!}(n - p)^p$$

In the single assignment  $p$ -hub center problem, partial assignment is not allowed; so we have  $(n^4 + n^2)$  binary variables,  $X_{ijkm}$  and  $Y_{ik}$ .

Although the  $p$ -hub center problem is NP-hard, some moderate size problems can be solved to optimality by the optimization software. We develop our  $p$ -hub center model in GAMS and utilize the cplex solver (Appendix A). By using the GMAS model, we can

- Validate our formulation, and
- Obtain the optimal solutions for the small-size problems at least to compare the performance of our GA based heuristic.

## **CHAPTER 4**

### **4. THE GENETIC ALGORITHM-BASED METHOD**

The p-hub center problems are proved to be NP-Hard (Ernst et al., 2009), even the allocation part of the problem is proved to be NP-Hard when the hub locations are given (Ernst et al., 2002b). Although the mathematical models guarantee the optimum solutions, only some small sized problems can be solved to optimality. However, the real life applications are usually large-sized ones and cannot be solved to optimality in a reasonable amount of time. Hence, heuristic solution approaches are developed. Greedy heuristics, tabu search, simulated annealing, lagrangean based heuristics and genetic algorithms are some of the heuristic approaches that have been developed for the location problems.

After reviewing the literature, we have decided to develop our own solution method based on the genetic algorithm (GA). In this chapter we explain GA-based method in detail. First, a brief review of the genetic algorithms with some basic concepts and definitions is given. Then, different phases and parameters of the proposed genetic algorithm are included in this chapter.

#### **4.1 GA-Based Heuristics**

Basically, GAs are one of the metaheuristic search methods based on the evolution process and natural selection principles in the nature with the concept of “survival of the fittest”. They are used for finding the near-optimal solutions by allowing solutions to evolve iteratively to good ones. GAs

were first introduced by John Holland, his colleagues and students at the University of Michigan (Goldberg, 1989) and developed by Goldberg (1989). GAs can solve hard problems both quickly and reliably; they are easy to interface to existing simulation models and mathematical models, are extensible and they are easy to hybridize (Goldberg, 1994). In the last three decades, GAs have emerged as effective, robust optimization and search methods (Kratica et al., 2007). They have been successfully applied in solving a variety of optimization problems that are difficult to solve, including the travelling salesperson problem, job-shop scheduling problems, vehicle routing problems, airline crew scheduling problems, optimizing the sequence of advertisements within a commercial break at a British television station, and painting trucks at a General Motors production facility to name a few (Chaudhry et al., 2000). GAs are also used for solving the location and hub location problems such as simple plant location problem (Kratica et al., 2001), dynamic facility layout problem (Dunker et al., 2005), uncapacitated single allocation  $p$ -hub median problem-USApHMP (Kratica et al., 2007), uncapacitated hub location problem (Abdinnour-Helm, 1998), uncapacitated single allocation hub location problem-USAHP (Topçuoğlu et al., 2005) and uncapacitated multiple allocation  $p$ -hub center problem-UMApHCP (Kratica and Stanimirovic, 2006).

It is important to design the genetic algorithms and its components based on the problem specific characteristics. The components of the GAs that must be defined properly are basically as follows:

- Representation of the chromosomes
- Parameter determination such as population size, crossover and mutation rates, maximum number of offspring to be generated
- Initial population generation
- Fitness function evaluation

- Evolutionary process of genetic operators, parent selection, crossover, mutation and replacement strategies.

## 4.2 The Proposed GA Method

The components of the GAs and how they are adopted to our  $p$ -hub center problem are explained in detail in the following sections.

### 4.2.1 Representation of the Chromosomes

Chromosome representation is very critical for the success of the GA heuristic in terms of the ability to represent the possible solutions and to avoid the infeasible solutions in the population. For instance, in the early studies related to the  $p$ -median problem, representations which show only the open and closed facilities without restricting the number of facilities is used and this ends up with more or less facilities than the desired number of facilities (Özgönenç, 2006).

The chromosomes can be coded with two representation schemes: (i) binary scheme and (ii) non-binary scheme. In the binary scheme coding 0s and 1s are used and any integer value is converted to base 2 with bits of 0 and 1s. Since to apply most of the operators of GA is easy in binary coding, it is used for most types of problems.

However, in several problem environments, it is more appropriate to use integer representations in order to cover all the related information of the problem environment in a chromosome. In this case, more attention should be given while designing the problem-specific genetic operators according to the integer representation of the chromosomes.

In our study, we have chosen the non-binary coding for chromosome representation of our problem. For an  $n$ -node problem with  $p$  hubs, each

chromosome of our GA method consists of  $n$  genes and each gene represents the nodes in our network. Each gene in the chromosome can take a value between 1 and  $n$  which shows the hub that the node is assigned to in that solution. A possible network scheme and the related chromosome coding for a feasible solution of 5 nodes and 2 hubs can be seen in Figure 4.1.

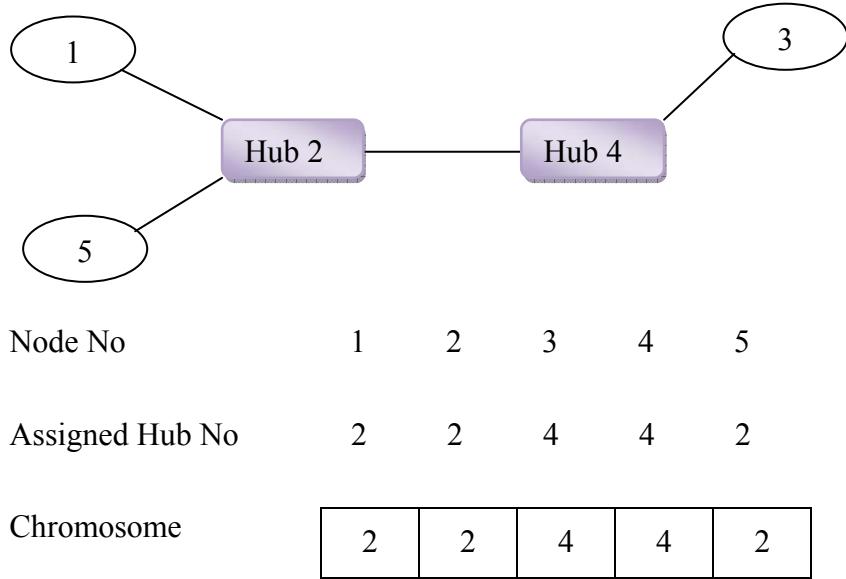

Figure 4.1 Example: Chromosome Representation of the proposed GA

In the above example representation, we have 5 nodes, and 2 nodes are chosen among them as the hubs. The remaining non-hub nodes and the hub nodes themselves are assigned to these two hub nodes. As a result, nodes 2 and 4 are chosen as the hubs and nodes 1, 2 and 5 are assigned to hub node 2, and nodes 3 and 4 are assigned to hub node 4 in the example representation above. To represent the feasible solutions, the important points in our problem for the chromosome representation are that, the hub nodes chosen in each chromosome should be strictly equal to  $p$  and the chosen hub nodes should be

assigned to themselves. These two conditions are satisfied while coding our GA method. The single assignment assumption of our  $p$ -hub center problem is satisfied implicitly with our chromosome representation.

#### **4.2.2 Initial Population Generation**

The search of the GA method starts with and continues by using the members of the initial population. The importance of the initial population is that, every possible solution to the problem can be attained from the solutions in the initial population by the genetic operators.

Usually, the initial population is generated randomly without any control on the diversity among the members of the population, so the individuals generated in this way may not cover the solution space entirely. So, the use of some control on the members of the population and the inclusion of problem specific knowledge to prevent a fully randomized population generation will provide some advantages.

The whole search space of our problem is very large especially for large problems, so narrowing the solution space according to our constraints is very crucial. Considering constraint (3.3) of our model, there are some assignments which can easily be shown to be infeasible. A non-hub node cannot be assigned to a hub having a travel time longer than  $L$ . So the potential hub locations that each node can be assigned to are obvious before the chromosomes are generated randomly. The non-hub-node pair  $i-j$ , having a total flow greater than the lower limit  $Q$  and having a mean travel time lower than  $H$ , that should satisfy constraint (3.2) are also known before the random generation.

After the elimination of some values using the information above, the values each gene in a chromosome can take are determined randomly. This process is repeated until the required population size is reached. During the population generation procedure, it is checked whether there is any duplication among the

individuals in order to maintain the diversity in the population. If there are any duplicates, the copy of the existing individual is not included into the population and a new non-identical individual is inserted instead.

The population generation ends up with the predetermined number of feasible members without any duplication.

Another issue about the population generation phase is the population size. Small population size might prevent genetic variety in the population. On the other hand, a very large population size may result in long CPU times to solve the problem. So, it should be a moderate size so as to allow population diversity and to prevent long solution times. There are several strategies to determine the population size; according to a traditional approach, the population size can be  $(n/p)$  and according to another approach by Alp et al. (2003) the population size based on the density approach can be defined as:

$$P(n,p) = \max \left\{ 2, \left\lceil \frac{n}{100} * \frac{\ln S}{d} \right\rceil \right\} * d$$

Where  $S = \binom{n}{p}$  is the total number of possible hub locations for the problem,  $d = \lceil n/p \rceil$  is the rounded density of the problem. In our GA method we use the second approach by Alp et al. (2003).

#### **4.2.3 Fitness Function Evaluation**

Although some other evaluation criteria can be used, the fitness function for a chromosome is generally the objective function value of the solution represented by the chromosome. As in many cases, the objective function values of the chromosomes are used as the fitness function value in our study. In our study, the objective function value is the maximum of the weighted travel times among all the node pairs, which is the summation of the weighted travel times from the nodes to the hubs that they are assigned to and the

discounted weighted travel time between the hub pairs. The information of the assignments of the nodes to the hubs is taken by decoding a chromosome, and the related weighted travel times and the discounted weighted travel times are calculated by some intermediate calculations for each pair of nodes. The maximum of these calculated travel times for each node pair is taken as the fitness function value of the chromosome.

#### 4.2.4 Parent Selection

After the generation of the initial population, the task of choosing parents to generate offspring that carries the properties from the parents as in the nature follows. There has been several parent selection techniques used in the literature. The selection techniques can be summarized as follows:

- Roulette-wheel Selection: Roulette is divided in slots and each individual possesses a part of the area of the roulette according to its fitness value. So, the individuals with higher fitness values have higher probability of selection.
- Stochastic Remainder Selection: In this selection method, a score is calculated for each individual in the population by dividing the fitness value of the individual with the average population fitness. Then each individual is replicated according to the integer part of these values and the fractional remainders are used as the probabilities of selection.
- Stochastic Universal Selection: Similar to the roulette wheel selection, again roulette is divided according to the fitness values. Equidistant markers are placed around the wheel as many as the number of required parents.
- Local Selection: Every individual is mated with an individual in the neighborhood defined with specific characteristics.
- Truncation Selection: All individuals are ranked according to their fitness values and only the fraction  $T$  (a predetermined threshold level)

best individuals can be selected having the same probability of selection.

- Tournament Selection: A number “Tour” of individuals are chosen randomly from the population and the individual with the best fitness value among these selected ones is chosen as a parent. The procedure continues until the required number of parents is chosen.
- Random Selection: Parents are selected randomly from the population and every individual has the same probability of selection.

In the nature, it is a fact that two genetically good parents yield a good child; it is not always true for the GAs. Sometimes two poor parents may generate an offspring with very good characteristics in terms of the solution to the problem. Although convergence of the algorithm takes time in the random selection method, the genetic diversity is kept in this method by giving the same importance to each chromosome. In this study we prefer to use random selection for our algorithm. Since the reproduction is repeated many times, many different individuals have the chance to be selected as parents and contribute to the diversification as well as the convergence of the population.

#### **4.2.5 Crossover**

Crossover is the phase where the genetic material, that is to say the information related to the problem, from two parents is combined to generate new offspring. Generally, either a single point crossover or two-point crossover is applied to the parents in GA applications. The parent chromosomes are split into two or three parts and these parts are exchanged between the parents creating new chromosomes. A classic two-point crossover is shown in Figure 4.2.

|             |    |   |   |   |    |    |    |   |   |    |    |
|-------------|----|---|---|---|----|----|----|---|---|----|----|
| Parent 1    | 2  | 5 | 1 | ↓ | 7  | 11 | 15 | 8 | ↓ | 13 | 18 |
| Parent 2    | 11 | 6 | 4 | ↓ | 12 | 17 | 9  | 2 | ↓ | 16 | 10 |
| Offspring 1 | 2  | 5 | 1 |   | 12 | 17 | 9  | 2 |   | 13 | 18 |
| Offspring 2 | 11 | 6 | 4 |   | 7  | 11 | 15 | 8 |   | 16 | 10 |

Figure 4.2 A Two-Point Crossover

Beside the traditional crossover explained, problem-specific knowledge can be inserted into the algorithm for the crossover phase. In our methodology, we design our own crossover for the  $p$ -hub center problem instead of using the traditional operators. After the parents are selected, the union of the hubs in both parents is taken and the common hubs repeated in both parents are taken as the frozen hubs for both children as in Alp et al. (2003). Say we have  $n$  nodes and  $p$  hubs in our problem, and  $m$  hubs are common. So we have a union of  $(2p-m)$  hubs and take  $m$  hubs as frozen. Then we need  $(p-m)$  more hubs to be selected for each child among the  $(2p-2m)$  remaining hubs in the union. In this case, we evaluate the alternatives for the hub selection; which yields  $C_{(2p-2m)}^{(p-m)}$  alternatives. For each alternative hub combination, we assign the hub nodes to themselves and evaluate the alternatives according to their fitness function. The two children with the better fitness functions are selected and replace the parents in the population. If no such child can be found with these parents, the parent pair is changed by the algorithm.

#### **4.2.6 Mutation**

Another component of the genetic algorithm that is used to maintain diversity in the population is mutation. It is used to avoid quick convergence or local optimum trap by randomly changing some existing genes of some chromosomes.

In our solution, to apply the mutation operator to our problem, a chromosome is selected randomly among the parents that do not contribute to the crossover part and one of the hubs of that chromosome is selected again randomly as in a standard mutation operator. This selected hub is replaced with the nearest non-hub node and the non-hub nodes assigned to the original hub are assigned to this new hub. At this step, we need to include some problem-specific corrections when needed. The necessary correction is done to assign this new hub to itself. For example, say the original hub node 2 is selected randomly and the non-hub nodes assigned to it are 1, 2 and 6. If the nearest non-hub node to 2 is 3, then instead of node 2, node 3 becomes the new hub and the nodes 1, 2 and 6 are assigned to it. Since node 3 was not formerly assigned to node 2, a correction is needed to assign new hub node 3 to itself.

#### **4.2.7 Termination**

Mainly, the GAs are terminated when a predetermined number of iterations is reached. One of the termination criterion used is  $n\sqrt{(n - p)}$  iteration counter. Purely using the predetermined number of iterations for termination may sometimes result in unnecessary computational time, since an exact convergence may occur earlier. For this reason, another criterion can be added to the algorithm for the successively repeated solutions.

#### **4.2.8 The Overall Algorithm**

The components of our GA method and how they are implemented are explained in detail; in the previous sections. The overall algorithm then can be summarized as:

- (1) Read the problem data and generate the initial population with the determined chromosome representation and the feasible members according to the constraints without any duplication among the members.
- (2) Evaluate the fitness function of each member in the initial population and record the best fitness value of the population,
- (3) Apply crossover to the selected parents of the initial population. Check the feasibility of the offspring and check the fitness values of the offspring for inserting to the population.
- (4) Apply mutation to the selected members of the initial population.
- (5) Update the best fitness value of the population.
- (6) Check the stopping criterion, if it is satisfied stop the algorithm, else to go to step 3.

The overall algorithm is also given in the following flowchart in Figure 4.3.

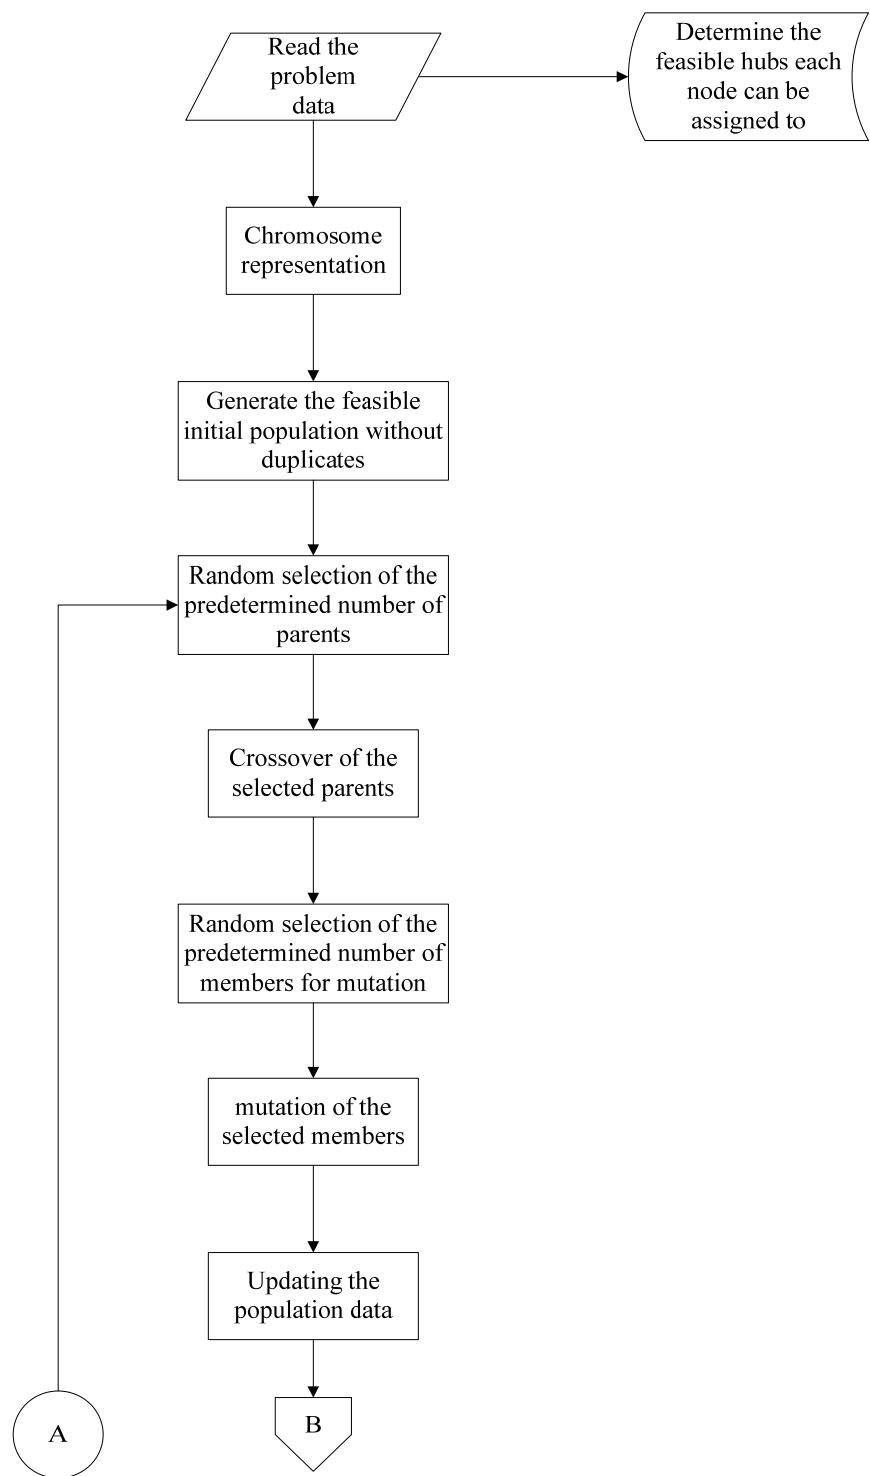

Figure 4.3 The Flowchart of the Algorithm

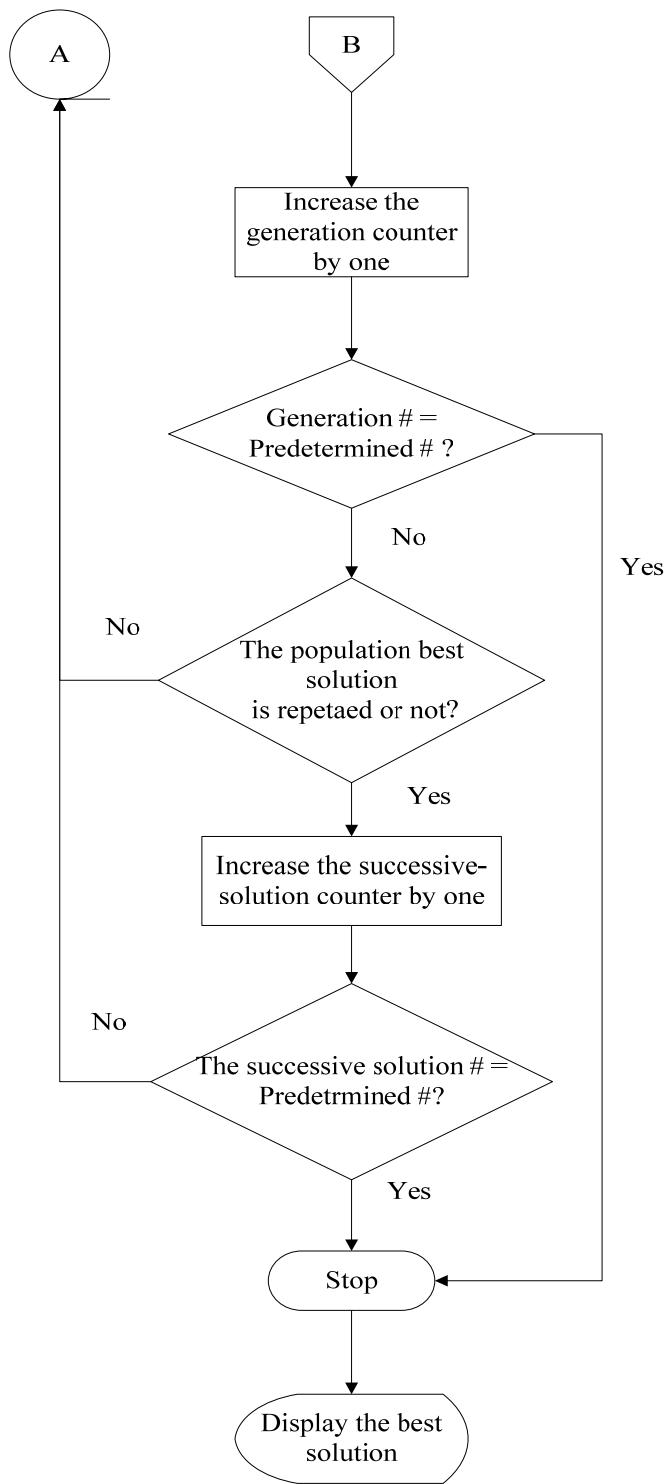

Figure 4.3 (cont'd)

## **CHAPTER 5**

### **5. COMPUTATIONAL STUDY**

In this chapter, the accuracy and the validity of the proposed GA method for our model are evaluated. This evaluation has three phases:

- Finding and generating appropriate problem instances
- Deriving the computational results with the proposed method
- Comparing the performance of the proposed method

#### **5.1. Test Data and Problem Instances**

As we describe, the elements of the problem environment that we deal with can be summarized as:

- Origin and destination node locations,
- Flow between each node pair,
- Travel time between each node pair,
- Potential hub locations.

As a result of our search on the test problems for hub location problem, one of the most commonly used test problems are the CAB data set in which the network has 25 nodes with the flow data and distance data between each pair of nodes. We have used the distance data as the travel time data in our model.

Other than the CAB data set, the Turkish network data, with the distance and time data taken as in Tan and Kara (2007) and flow data taken as in Çetiner, Sepil and Süral (2006), is used for testing our solution approach.

The districts-cities with their node numbers, the flow data and distance data between each pair of nodes are given in Appendix C for both data sets.

We generate new problem instances using the CAB data set and Turkish network data set by four different ways:

- (1) The first  $n$  entries of the data sets are taken in order to generate new  $n$ -node new networks.
- (2) The last  $n$  entries of the data sets are taken in order to generate new  $n$ -node networks.
- (3)  $n$ -nodes of the data sets are selected in order to generate new  $n$ -node networks.
- (4) The  $n$ -nodes with the maximum flows are taken from the data sets in order to generate new  $n$ -node networks.

A problem instance can then be defined by the characteristics as:

- The number of nodes.
- The number of hubs to be located.
- The way the network is generated.

For instance, the problem instance “CAB\_20\_4(1)” is the problem instance of 20-node CAB data set with 4 hubs, generated by the way (i) defined above, which means that the network is generated by taking the first 20 nodes of the CAB data set.

## 5.2. The Evaluation of the Proposed Method

The GA-based solution method proposed should be evaluated in terms of the objective function values observed and the CPU time used. There are several ways to evaluate a proposed solution method such as;

- Comparing the solutions of the proposed method with the proven optimal values from the literature.
- Comparing the solutions of the proposed method with the best known solutions.
- Comparing the results from the proposed method with a lower bound or an upper bound.

The mathematical model proposed in Chapter 3, is coded in GAMS solver to get the optimal solutions (Appendix A). However, as mentioned before, the  $p$ -hub center problem is NP-hard, and with so many variables and constraints, large sized problems are hard to solve with mixed integer programming solvers.

Another point worth mentioning about the evaluation of the model studied is that, although there exist a number of studies in  $p$ -hub center literature, the problems studied are not exactly defined as our  $p$ -hub center problem.

When the conditions above are considered, we conclude that in order to evaluate the performance of our solution method, some heuristic solutions should be obtained for comparison. The model generated in Chapter 3 has got several binary variables, and the mathematical models with binary variables are hard to solve with the commercial solvers available. So, relaxing the binary variables  $Y_{ik}$  is a way to get an upper bound for our problem. When we relax the binary variables, actually the resulting problem becomes multiple allocation  $p$ -hub center problem; and the resulting assignment variables which will take on values between 0 and 1, will show the percentage of the flows that is

assigned to a hub. However, relaxing binary variables is not enough for getting solutions for the large sized problems, since again multiple allocation p-hub center problems are NP-hard as mentioned in Ernst et al. (2002a).

Considering all of the above, in order to evaluate the performance of our solution method for the problems that cannot be solved by the GAMS solver, we have decided to use a sequential approach which handles the problem by solving two sub-problems sequentially. In this approach we first solve the constrained  $p$ -center problem for locating the hubs using GAMS and then determine the allocation of nodes to these given hubs. In the allocation phase of the approach; again we cannot use the single allocation  $p$ -hub center approach for given hubs; since even the allocation sub-problem of  $p$ -hub center problem is NP-hard when the hub locations are given (Ernst et al., 2002b). However, the single allocation phase is polynomially solvable, when  $\alpha=0$  on a hub-complete graph (Campbell et al., 2007). So, for the location phase of the approach we use the  $p$ -center problem, and for the allocation phase we assume that  $\alpha=0$  between the hubs and find the assignments of the nodes to the given hubs and call this overall approach as ALL. When  $\alpha$  is assumed to be zero, this means the objective function of our model reduces to:

$$“W_{ij}(t_{ik} Y_{ik} + t_{jm} Y_{jm})”.$$

After finding the locations and allocations of the hubs and nodes using this approach, in order to be comparable with our objective function, we compute our original objective function which is  $W_{ij}(t_{ik} Y_{ik} + \alpha t_{km} + t_{jm} Y_{jm})$  for the resulting network.

Another approach to get a solution to compare our method is the aggregation method. Aggregation is the assignment of several points to a single representative point (Gavriliouk, 2009). According to Gavriliouk, for an allocation problem that is difficult to solve in its original environment, the

points in the original environment can be aggregated, and the same location problem can be solved in the aggregated environment with a less number of nodes. The solution of the aggregated environment can be transferred into the original environment. For finding another solution value we decide to aggregate our nodes. In the Turkish network data set, we apply an aggregation method according to the flow densities of the nodes and according to the travel times. In order to find a moderate sized network that we can model in GAMS, we order the nodes according to their flow densities in a descending manner, and determine the nodes that will be in the aggregated environment. Other nodes that will not be in the aggregated environment are assigned to the nearest node already determined to be in the aggregated environment. While doing the aggregation, we sum up the flows of the aggregated nodes. Then we use this aggregated environment to solve our original  $p$ -hub center problem. After finding the locations of the hubs and allocations of the aggregated nodes, we disaggregate the aggregated nodes and assign them to the hubs, we call this approach as AGG. Again as in the ALL heuristic explained above, we compute our original objective function value  $W_{ij}(t_{ik}Y_{ik} + \alpha t_{km} + t_{jm}Y_{jm})$  for the resulting network.

As a result, for the small problem instances that can be solved to optimality with GAMS, we compare the performance of our solution method with the optimal results that we get from GAMS. For large problem instances that we cannot solve with the commercial optimization solvers, we use the results from the heuristic approaches AGG and ALL. We perform 10 runs with our GA method for each problem instance; the individual results of these runs for each problem instance are given in Appendix D.

### 5.2.1 Small Problem Instances

In this section we study on small problem instances from the Turkish network data set and CAB data set. The CAB data consist of 25 node network and we

generate four different sized problem instances as CAB\_25, CAB\_20, CAB\_15 and CAB\_10. For the 20-node, 15-node and 10-node CAB data set instances we use the four generation methods mentioned above to generate new problem instances. On the other hand, the Turkish network data consists of 81 nodes and the whole network cannot be solved using GAMS. As a result, again we get small sized problem instances as Turk\_30, Turk\_25 and Turk\_20 from Turkish network data set again by using the four problem generation methods.

We consider the results of the CAB data set and the Turkish network data set in the following sections below.

#### **5.2.1.1 Small Problem Instances of the CAB Data Set**

For the CAB data set, we construct four different sized problem instances. The parameters in the problem environments should be problem specific and should be determined accordingly. Because of the network structure of the CAB data set, we start our computational studies on CAB data set with the corresponding parameters:

- L=650 minutes
- H=960 minutes
- $\beta=1,440$  minutes
- Q=200,000
- $\alpha=0.90$
- $\gamma=0.95$
- CV=0.80

However, for some problem instances with these parameters, the problem turns out to be infeasible because of the constraints. In these cases, we change the parameters one by one ceteris paribus if not mentioned, starting with the parameter  $\gamma$  and then the given  $p$  value.

The results obtained for the problem instances of the CAB data are given in Table 5.1.

For the problem instance, CAB\_20\_5(4), the problem is infeasible with the parameters above. So we decrease the  $\gamma$  value to 0.85 and then solve the resulting problem. Decreasing the probability level makes the problem feasible, because the higher the  $\gamma$  value, the higher the  $z_\gamma$  value; so the right hand side of the constraint (3.2) will be higher and it becomes larger than the specified  $\beta$  value for some node pairs:

$$\beta \geq X_{ikm}(t_{ik} + \alpha t_{km} + t_{jm} + z_\gamma \sqrt{\sigma_{ik}^2 + \alpha^2 \sigma_{km}^2 + \sigma_{jm}^2}) \quad (3.2)$$

For the problem instance CAB\_15\_4(2), the problem is again infeasible, and we decrease the  $\gamma$  value first to 0.85. However, the problem is still infeasible with these parameters. Actually the problem is infeasible even for  $\gamma=0.70$ . As a result, the given number of hubs is not sufficient to meet the service level constraint. We increase the  $p$  value from 4 to 5, other parameters being the same as they were at the beginning. With  $p=5$  the service level constraint can be met and the problem becomes feasible. The results Table 5.1 are given for this problem instance as CAB\_15\_5(2).

The problem instance CAB\_15\_4(4) is again an infeasible problem for the given parameters. However, when the  $\gamma$  value is decreased to 0.85 the problem becomes feasible, and the results are given in Table 5.1 for this problem instance with  $\gamma=0.85$ .

Another infeasible problem instance with CAB data set is CAB\_10\_3(2), and it is even infeasible for  $\gamma=0.70$ . So, we increase the  $p$  value from 3 to 4; however the problem is still infeasible for  $\gamma=0.95$ . When the  $p$  value is increased to 5, the resulting problem become feasible and the solutions are given in Table 5.1 for CAB\_10\_5(2).

For the infeasible problem instance CAB\_10\_3(3), first we decrease the  $\gamma$  value until 0.70, but the problem is still infeasible. So, the  $p$  value is increased to 4 with the given parameters at the beginning of the section, and the solutions of the resulting problem instance are given in Table 5.1 for CAB\_10\_4(3).

The last small sized problem instance generated from the CAB data set is CAB\_10\_3(4), and it is again infeasible with the starting parameters. The problem instance remains infeasible although, the  $\gamma$  value is decreased to 0.70. For  $p=4$  when other parameters remain unchanged, the problem is infeasible, but when the  $\gamma$  value is decreased to 0.85, the problem results with feasible solutions which are given in Table 5.1 as CAB\_10\_4(3). For this problem instance, when we increase the number of hubs to 5, we can get feasible solutions, although the  $\gamma$  value is not decreased with an objective function value of 51.172. There is a trade-off between the number of hubs and the probability of service level guarantee. If a higher service level guarantee, 0.95, is desired then the hub number should not be smaller than 5; however if the number of hubs cannot be more than 4, then the probability of service level guarantee cannot be greater than 0.85. The decision maker should decide on these conflicting decisions.

Table 5.1 Comparison of GAMS and GA Results for the CAB Data

| Problem Instances | GAMS Results        |                           | GA Results               |                             |                            |
|-------------------|---------------------|---------------------------|--------------------------|-----------------------------|----------------------------|
|                   | Obj. Function Value | Computational Time (Sec.) | Best Obj. Function Value | Average Obj. Function Value | Range of Comp. Time (Sec.) |
| CAB_25_5          | 32.993              | 2,139                     | 32.993                   | 33.599                      | [69,83]                    |

### **5.2.1.2 Small Problem Instances of the Turkish Network Data Set**

For the Turkish Network data set, we generate three different sized small problem instances. As for the CAB data set, the parameters in the problem environments should be problem specific and should be determined accordingly. Because of the network structure of the Turkish network data set, we start our computational studies on the CAB data set with the corresponding parameters:

- L=480 minutes
- H=960 minutes
- $\beta=1,440$  minutes
- Q=200,000
- $\alpha=0.90$
- $\gamma=0.95$
- CV=0.80

However, for some problem instances with these parameters, the problem instances become infeasible because of the constraints. In these cases we change the parameters one by one *ceteris paribus* if not mentioned, starting with the parameter  $\gamma$  and then the given  $p$  value.

The results obtained on the small problem instances of the Turkish Network data are given in Table 5.2. In Table 5.2 below, it is obvious that the computational time may become high with a small increase in the network in GAMS solver.

For Turk\_30\_6(1) network the computational time is more than 12 hours and the solution cannot be proved to be optimal by GAMS and it is in a relative gap of 0.669 (and absolute gap of 10.810). As a result our GA result is better than the GAMS result for our problem.

Again for the Turk\_30\_6(2) the given GAMS solution is not proven optimal solution, it is in a relative gap of 0.196 and an absolute gap of 1.453 and the program ends up with out of memory warning.

For the problem instance, Turk\_30\_6(4), the problem is infeasible with the initial parameters. So, we decrease the  $\gamma$  value to 0.85 and then solve the resulting problem. Decreasing the probability level makes the problem feasible, because the higher the  $\gamma$  value, the higher the  $z_\gamma$  value. In Table 5.2, the solutions for the Turk\_30\_6(4) are given for  $\gamma=0.85$  and the solution of the GAMS is not proven to be the optimal solution, although the program runs for more than 26 hours. The solution is in a relative gap of 0.504.

For the 25 node Turkish Network data set obtained by the problem generation method (3), the problem is infeasible for  $p=5$  and  $\gamma=0.95$ . The problem becomes feasible for  $\gamma=0.85$  and the related solutions are given in Table 5.2. According to the network characteristics, there is a lower limit on the number of hubs that should be satisfied in order for the problem to be feasible. The  $\gamma$  value is about the service level constraint, and decreasing it makes the constraint loose. Another constraint in our problem is the constraint (3.3) that forces to end up with the number of hubs greater than a threshold level. For instance, the Turk\_25\_5(3) problem is infeasible for  $L=480$ ; however, when we increase  $L$  to 520, the problem becomes feasible.

The Turk\_25\_5(4) problem instance is feasible for the initial parameters, and it is solved for  $\gamma=0.80$  which is a feasible network structure ceteris paribus.

The Turk\_20\_4(4) is a feasible network for  $\gamma=0.75$  with the solutions given in Table 5.2. If the number of hubs for this problem is increased to 5, then the network structure becomes feasible for the service level probability  $\gamma=0.85$ . Again in the case of CAB\_10\_3(4) problem instance, we face with a tradeoff between the number of hub and the probability of service level guarantee. The decision should be made whether to have a network with 4 hubs and to be sure with 0.75 probability that the deliveries for the specified node pairs will be

made in  $\beta$  minutes; or to have a network with 5 hubs and to be sure with 0.85 probability that the deliveries for the specified node pairs will be made in  $\beta$  minutes.

Table 5.2 Comparison of GAMS and GA Results for the Small Turkish Network Problem Instances

| Problem Instances | GAMS Results        |                           | GA Results               |                             |                            |
|-------------------|---------------------|---------------------------|--------------------------|-----------------------------|----------------------------|
|                   | Obj. Function Value | Computational Time (Sec.) | Best Obj. Function Value | Average Obj. Function Value | Range of Comp. Time (Sec.) |
| Turk_30_6(1)      | 16.161              | 45,808                    | 10.590                   | 12.751                      | [1,006;1,224]              |

| Turk_30_6(3)      | 7.398               | 1,321                     | 6.549                    | 8.054                       | [692,983]                  |
| Turk_30_6(4)      | 12.057              | 95,713                    | 8.981                    | 10.791                      | [1,024;1,802]              |
| Turk_25_5(1)      | 10.483              | 5,382                     | 10.483                   | 12.251                      | [44;21]                    |
| Turk_25_5(2)      | 12.577              | 6,626                     | 12.577                   | 14.237                      | [157;203]                  |
| Turk_25_5(3)      | 22.922              | 1,812                     | 22.922                   | 24.664                      | [108;218]                  |
| Turk_25_5(4)      | 8.592               | 8,150                     | 8.592                    | 10.617                      | [145;287]                  |
| Turk_20_4(1)      | 12.926              | 684                       | 12.926                   | 13.360                      | [24;48]                    |
| Turk_20_4(2)      | 14.963              | 232                       | 14.963                   | 20.004                      | [37;54]                    |
| Turk_20_4(3)      | 19.471              | 25,243                    | 19.471                   | 21.786                      | [124;187]                  |
| Turk_20_4(4)      | 11.666              | 144                       | 11.666                   | 12.760                      | [78;92]                    |

### **5.2.2 Large Problem Instances**

For the large problem instances, we use the Turkish network data set. Again we use four different problem generation methods, as the small problem instances to generate different large sized problem instances. As we mention before, the large sized problems cannot be solved with GAMS to optimality. To compare the performance of our solution method for large problems, we use the heuristic approaches which we call AGG and ALL.

In the heuristic approach AGG, we aggregate the nodes to get smaller problem instances. We assign the nodes with small flows to the nearest node that will exist in the aggregated environment, and solve our problem in this aggregated environment. Then we disaggregate the resulting nodes and calculate the objective function value accordingly.

In ALL heuristic approach, in the first phase, we solve  $p$ -center problem to find the location of the hubs. The hubs found in the location phase are used as given in the allocation phase. For the allocation phase, we assume the discount factor  $\alpha=0$  between the hubs, and find the assignments of the nodes to the given hubs.

For the large sized problem instances with the Turkish Network data set, we generate three different sized problem instances. The results obtained for the large sized problem instances of the Turkish Network data are given in Table 5.3.

Table 5.3 Comparison of GAMS and GA Results for the Large Turkish Network Problem Instances

| Problem Instances | AGG Results         |                           | ALL Results         |                           | GA Results               |                             |                            |
|-------------------|---------------------|---------------------------|---------------------|---------------------------|--------------------------|-----------------------------|----------------------------|
|                   | Obj. Function Value | Computational Time (Sec.) | Obj. Function Value | Computational Time (Sec.) | Best Obj. Function Value | Average Obj. Function Value | Range of Comp. Time (Sec.) |
| Turk_81_12        | 7.836               | 47,225                    | 7.957               | 32                        | 4.890                    | 6.357                       | [3,161;3,648]              |

| Turk_60_9(2)      | 16.317              | 7,347                     | 14.337              | 35                        | 8.481                    | 9.833                       | [1,874;2,124]              |
| Turk_60_9(3)      | 14.395              | 9,502                     | 11.876              | 37                        | 7.876                    | 8.905                       | [1,584;1,894]              |
| Turk_60_9(4)      | 9.430               | 4,347                     | 10.147              | 39                        | 6.429                    | 7.747                       | [1,145;2,048]              |
| Turk_50_8(1)      | 11.047              | 1,478                     | 13.302              | 21                        | 10.348                   | 13.841                      | [1,084;1,478]              |
| Turk_50_8(2)      | 19.439              | 2,038                     | 21.239              | 24                        | 13.318                   | 15.197                      | [1,148;1,847]              |
| Turk_50_8(3)      | 16.846              | 1,784                     | 14.471              | 28                        | 12.310                   | 13.453                      | [1,245;1,905]              |
| Turk_50_8(4)      | 10.806              | 1,547                     | 9.904               | 31                        | 6.096                    | 7.557                       | [1,147;1,284]              |

The GA algorithm based heuristic method that is proposed results in very good solutions in a very short time. Although the algorithm does not always end up with the optimal solutions, instead of having a single solution to a problem, usually it is preferable to have alternative good solutions for the decision makers. The algorithm enables us to analyze a set of alternative good solutions for a network.

### 5.3 Extensions about the Model

After evaluating our solution method in the previous sections, we want to introduce the effects of the constraints and the parameters used in the solutions, we deal with the problem instance Turk\_25\_5.

First we solve our problem for different  $p$  values, the number of hub values. As can be seen in Table 5.4, the constraints we impose in our model, the constraint on the service level and on the travel time between the nodes and hubs indicate that there should be at least 4 hubs in order for the network to be feasible. When  $p=3$ , the constraints are not satisfied, and for  $p=4$  and higher, the problem is feasible. After  $p=5$ , the objective function does not change.

Table 5.4 The Effects of the Number of Hubs,  $p$ ,

| $p$ | Obj. Function Value | Computational Time | Selected Hubs    |
|-----|---------------------|--------------------|------------------|
| 3   | Infeasible          | -                  | -                |
| 4   | 12,481              | 3.271              | 6,12,15,17       |
| 5   | 10,483              | 5.382              | 6, 7, 13, 14, 21 |
| 6   | 10,483              | 6.452              | 3,6,12,18,21,22  |
| 7   | 10,483              | 2.850              | 4,5,6,7,11,16,21 |
| 10  | 10,483              | 5248               | 10,11,18,21,22   |

As for the constant  $L$ , which is the restriction on the travel time between the hubs and non-hub nodes, the results for different values of  $L$  are given in Table 5.5. As in the case of  $p$ , infeasibility may be observed below a certain level for  $L$  values. This is because of the structure of the network that is there cannot be any hub assignments for some cities that satisfy  $L$ , for small values. The threshold level below which infeasibility results, depends on the structure of the network; so the level of  $L$  should be problem-specific. In our problems, increasing  $L$  decreases the value of the objective function, because small values of  $L$  eliminates some of the alternatives for the hubs; while decreasing the travel time between the hubs and non-hub nodes with  $L$ , the maximum weighted travel time is increased. Although  $L$  is increased, the objective function value does not change after a certain level; but we get different hubs selected. This is because of the alternative optima nature of the  $p$ -hub center problems. Actually, by varying the parameter  $L$ , we chose a well structured alternative optimal solution.

Table 5.5 The Effects of  $L$  on the Solution

| $L$ | Obj. Function Value | Computational Time (Sec.) | Selected Hubs |
|-----|---------------------|---------------------------|---------------|
| 300 | Infeasible          |                           |               |
| 360 | 15,195              | 6792                      | 1,6,16,20,25  |
| 420 | 12,481              | 8784                      | 1,3,6,11,12   |
| 480 | 10,483              | 5.382                     | 6,7,13,14,21  |
| 540 | 10,483              | 7260                      | 6,11,14,21,25 |
| 780 | 10,483              | 18.716                    | 1,3,6,7,21    |

To sum up, the  $p$ -hub center problem has alternative optimal solutions and with the constraints we imposed, we try to get a well structured solution among the

alternative optimal solutions. The p-hub center problems try to minimize the maximum travel times or costs. However, when minimizing the maximum path, many of the paths become trivial and actually the optimal solutions occur as a result of this. For instance in Figure 5.1 and Figure 5.2, networks with 5 nodes and 2 hubs are demonstrated. Assuming that the path from node A to node D is the longest one to be minimized, in terms of the objective function value, the two networks are similar. However, when the path from node E to node D is considered, the two networks have difference in terms of their travel time or cost. In Figure 5.1, the node E is assigned to the hub C, and the flows between E and other two nodes A and D should be transferred through hubs C and D. However, in Figure 5.2 the node E is assigned to hub B and the flows between node A and the other two nodes are transferred via hub B only. Although the two networks are indifferent in terms of the objective function values, the second one is a better structured network.

#### 5.4 The Effects of the Coefficient of Variation to the Solution

Up to now, for the computational analysis we use 0.80 for the value of the coefficient of variation. The real travel times of the data set sets are taken as the mean travel times; the standard deviations are calculated with these mean values and the coefficient variation value of 0.80. The value of the coefficient of variation changes the variability of the distributions. The greater the coefficient of variation, the more variable is the distribution. In order to see the effects of different coefficients of variations, we use two more values for it; 0.30 and 0.50 other than 0.80 which was originally used. The coefficient of variation value is used in constraint (3.2) in order to calculate the standard deviations from the mean travel times. Since  $CV = \sigma/\mu$ , the higher the coefficient of variation the higher the variability of the distribution and the higher the standard deviation. Higher coefficient of variation and consequently higher standard deviation cause constraint (3.2) to be tighter. In Table 5.6 we present the solutions obtained at three levels for CV, using GAMS.

Table 5.6 The Effects of Different Coefficient of Variation Values on the Solutions

| Problem Instances | CV=0.80             |                | CV=0.50             |                | CV=0.30             |                |
|-------------------|---------------------|----------------|---------------------|----------------|---------------------|----------------|
|                   | Obj. Function Value | Selected Hubs  | Obj. Function Value | Selected Hubs  | Obj. Function Value | Selected Hubs  |
| CAB_20_5(4)       |                     | Infeasible     | 32.486              | 1,11,12,20,23  | 32.486              | 1,11,12,20,23  |

## CHAPTER 6

### 6. CONCLUSIONS AND DIRECTIONS FOR FUTURE STUDY

In this study we have searched the solution techniques for the uncapacitated, single allocation p-hub center problem with service level constraints. First, we have presented the mathematical formulations for our problem environment. We try to represent the real life environment of the cargo delivery systems while constructing our model. The NP-hard nature our mathematical model and the difficulty in obtaining the optimal solutions for the reasonable sized problems led us to search on the applications of metaheuristics.

In our GA-based solution method, we have developed genetic algorithms based solution approach with problem specific characteristics. The developed algorithm has been implemented to problem instances constructed from CAB data set and the Turkish network data set. The results for small problem instances were compared with the optimal results we get from GAMS solutions. For the large sized problems, in order to get comparable solutions, we did aggregation and decomposition. In aggregation method we aggregated the nodes with few flows with the nearest nodes with higher flows and solved the aggregated problem with GAMS solver again. In the decomposition of the problem, we solve two sub-problems; location and allocation problems. In the allocation phase, we solve the  $p$ - center problem and find the locations of the hubs for the network. In the allocation phase, the hubs found from  $p$ -center problem are used as given and the nodes are allocated to the hubs assuming that  $\alpha=0$ . The computational results on different problem instances show that our GA based heuristic approach produces good results both in terms of the

objective function value and the computational time. The heuristic approach proposed ends up with alternative optimal solutions and near optimal solutions, in a reasonable amount of time. We get a set of different good solutions and in many situations having a set of alternative good solutions is preferable by the decision makers.

For further research on the solution method proposed; other problem specific operators apart from those used in this study may be generated and evaluated. Moreover, additional improvements on the problem specific characteristics may be included in different phases of the solution method. The coding of the GA proposed here can be improved further.

For the stochastic travel times of the problem environment; different distributions other than the normal distribution can be used. Since in the real life applications, the stochastic behavior of the travel times change from link to link, different node pairs may be considered as having different variability. For the capacitated case of the problem, variability in the demand may also be incorporated to the problem.

As mentioned before, the  $p$ -hub center problems have alternative optimal solutions; however, the structures of the networks among these alternative optimal solutions are different. In this study, we try to select the well structured ones. Other criterion about this point can be introduced for  $p$ -hub center problems.

Incremental increases in the number of hubs do not contribute to our objective function value, which is the maximum weighted travel time, after a threshold level. However, having more hubs in a network may decrease the total travel times of the network. There is a trade-off between the number of hubs opened and total travel time of the networks. Additionally, relaxing the restriction on the travel times between the hub nodes and non-hub nodes decreases the

maximum weighted travel time. The cost of travel between a non-hub node and a hub node is not identical with the cost of travel between the hubs. So, analysis considering these points can be done for the number of hubs to be opened, and the total network travel times and the traveling time between non-hub nodes and hub nodes and between the hub nodes.

In this study, we only considered the travel times. Multi-criteria models that take into account both the travel times and costs can be developed.

## APPENDIX A

### GAMS MODEL

The mathematical model formulations translated to GAMS with the definition of the elements of the model, the objective function and the constraints are presented below.

#### **Linear Model for the P-Hub center Problem with Stochastic Service Level**

##### **Constraints:**

###### **Sets**

i origin nodes;  
j destination nodes;  
k possible origin hubs ;  
m possible destination hubs ;

###### **Parameters**

W(i,j) the flow weight between origin node i to destination node j ;  
F1(i,j) the flow from origin node i to destination node j ;  
F2(j,i) the flow from origin node j to destination node i ;  
T(i,j) standard travel time on the link from node i to node j ;  
t1(i,k) travel time from node i to hub k ;  
t2(k,m) travel time from hub k to hub m ;  
t3(m,j) travel time from hub k to hub m ;

Display i,j,k,m,W,T,t1,t2,t3 ;

## Scalars

scalar P number of hubs // ;  
scalar a discount factor // ;  
scalar b targeted service level for specified node pairs // ;  
scalar s standard normal z value // ;  
scalar cv coefficient of variation // ;  
scalar L restriction on the travel times between nodes and hubs // ;  
scalar Q flow threshold for the service level applicability // ;  
scalar H travel time threshold for the service level applicability // ;

## Variables

z maksimum weighted travel time from node i to node j ;  
binary variable X(i,j,k,m) ;  
\*==== 1, if there is a path from origin node i to destination node j via the hubs k  
and m / 0, otherwise  
binary variable X1(i,k) ;  
\*==== 1, if node i is assigned to hub k / 0, otherwise  
binary variable X2(j,m) ;  
\*==== 1, if node j is assigned to hub m / 0, otherwise  
binary variable X3(k,k) ;  
\*==== 1, if node k is a hub/ 0, otherwise  
binary variable X4(m,m) ;  
\*==== 1, if node m is a hub/ 0, otherwise

## Equations

time(i,j,k,m) define the objective function ;  
total\_hub\_number1 satisfies the given hub number for k  
total\_hub\_number2 Satisfies the given hub number for m  
node\_hub\_assign1(i,k) No node is assigned unless there is a hub for k  
self\_assign1(i,k) A hub is assigned to itself for k

node\_hub\_assign2(j,m) No node is assigned there is a hub for m  
 self\_assign2(j,m) A hub is assigned to itself for m  
 exactly\_one\_hub1(i) Satisfies the assignment of node to a hub for k  
 exactly\_one\_hub2(j) Satisfies the assignment of node to a hub for m  
 path\_assignment1(i,j,k,m) Satisfies path assignment iff node to hub assignments exists  
 Single\_path(i,j) Satisfies single path assignment for every node pair  
 serv\_crit(i,j,k,m) Satisfies the service level criterion for selected hub pairs  
 equal(i,j,k,m) Satisfies the symmetry of the assignments  
 leg1(i,k) Restriction about the travel time between nodes and hubs i and k  
 leg2(j,m) restriction about the travel time between nodes and hubs j and m

```

time(i,j,k,m) .. z =g= (W(i,j)*X(i,j,k,m))*((t1(i,k)) + (a*t2(k,m)) + t3(m,j)) ;
total_hub_number1 .. sum((k), X3(k,k)) =e= p ;
total_hub_number2 .. sum((m), X4(m,m)) =e= p ;
node_hub_assign1(i,k) .. X1(i,k) =l= X3(k,k) ;
self_assign1(i,k)$(ord(i)=ord(k)) .. X1(i,k) =e= X3(k,k);
node_hub_assign2(j,m) .. X2(j,m) =l= X4(m,m) ;
self_assign2(j,m)$(ord(j)=ord(m)) .. X2(j,m) =e= X4(m,m);
exactly_one_hub1(i) .. sum((k),X1(i,k)) =e= 1 ;
exactly_one_hub2(j) .. sum((m),X2(j,m)) =e= 1 ;
path_assignment1(i,j,k,m) .. X(i,j,k,m) =g= X1(i,k) + X2(j,m) - 1 ;
single_path(i,j) .. sum((k,m),X(i,j,k,m)) =e= 1 ;
serv_crit (i,j,k,m) $((T(i,j) lt H) and ((F1(i,j) + F2(j,i)) gt Q)) .. b =g=
X(i,j,k,m)*((t1(i,k)+a*t2(k,m) + t3(m,j))+ (s*sqrt(sqrt(cv*t1(i,k))+sqrt(a)*sqrt(sqrt(cv*t2(k,m))+sqrt(cv*t3(m,j)))))) ;
equal(i,j,k,m)$(ord(i)=ord(j) and ord(k)=ord(m)) .. X1(i,k) =e= X2(j,m) ;
leg1(i,k) .. L =g= X1(i,k)*t1(i,k) ;
leg2(j,m) .. L =g= X2(j,m)*t3(m,j) ;
